Abstract

Functional analysis of variance (ANOVA) modeling has been proved particularly useful to investigate the dynamic changes of functional data according to certain categorical factors and their interactions. However, the current existing methods often encounter difficulties when the functional data are high-dimensional, non-Gaussian, and/or exhibit certain shape characteristics that vary with spatial locations. In this paper, we investigate the functional two-way ANOVA models from a novel Bayesian perspective. A class of highly flexible Gaussian Markov random fields (GMRF) are taken as priors on the functions in the model, which allows us to model various types of functional effects, such as (discrete or continuous) temporal effects and (point-level or areal) spatial effects. The resulting posterior distributions are obtained by an efficient computational tool based on integrated nested Laplace approximations (INLA) (Rue et al., 2009). We then employ the excursion method introduced by Bolin and Lindgren (2015) to build simultaneous credible intervals of functional effects and test their significance from a Bayesian point of view. A simulation study and multiple real data examples are presented to demonstrate the merits of our method.

Keywords: functional data; generalized ANOVA; Gaussian Markov random fields; integrated nested Laplace approximations; simultaneous credible intervals; contour avoiding functions.

1 Introduction

Functional data analysis plays an important role in modern statistics. Being associated with continuous time/space monitoring processes, functional data are usually a sample of curves or surfaces and are often treated as realizations of underlying random functions. The basic philosophy of functional data is to consider observed data functions as single entities, rather than only as a sequence of individual observations. Functional data are becoming increasingly common in a variety of scientific and medical areas. A considerable effort has been made in statistical fields to adapt standard statistical methods to functional data. The general ideas of functional data analysis were laid out by Ramsay and Dalzell (1991). Müller (2005) developed some concepts for estimating functional principal component scores in the sparse situation, and proposed an extension of the generalized functional linear models and functional logistic discrimination for the classification of functional data. Functional modeling methods have also become more and more popular in real applications. For instance, Wang et al. (2009) applied a functional random-effects model to human brain electroencephalogram (EEG) data. Comprehensive surveys of parametric and nonparametric techniques for analyzing functional data can be found in Ramsay and Silverman (2005) and Ferraty and Vieu (2006). Bayesian approaches to functional data analysis have also drawn increasingly attentions. Morris and Carroll (2006) proposed a Bayesian wavelet-based approach for functional mixed models. Crainiceanu and Goldsmith (2010) presented functional linear regression and functional principle component analysis using WinBUGS. Goldsmith et al. (2011) studied functional regression via variational Bayes.

This paper focuses on the analysis of variance (ANOVA) models for functional data, which have proven particularly useful when the functional data are expected to differ with certain categorical factors (see e.g., Faraway, 1997; Brumback and Rice, 1998). Let us start from a simple one-way functional ANOVA model, where there is only a single factor of interest. We denote, \( y_{ik}(x) \), the \( k \)th functional observation in the \( i \)th group, then the model can be expressed as

\[
y_{ik}(x) = \mu(x) + \alpha_i(x) + \varepsilon_{ik}(x), \quad x \in \mathcal{X} \subset \mathbb{R}^d,
\]

where \( \mu(x) \) is the grand mean function, \( \alpha_i(x) \) is the \( i \)th group effect function, and \( \varepsilon_{ik}(x) \)
is the residual function with mean zero, for \( i = 1, \ldots, m_A \) and \( k = 1, \ldots, n \). To be able to identify them, we require the group effect functions to satisfy certain constraint, e.g., \( \alpha_{m_A}(x) = 0 \) for all \( x \). There are two main questions we need to address in functional ANOVA: the first is “How do we estimate the functions in the model?” and the second is “How do we test the functional effects of various factors, e.g., test \( H_0 : \alpha_1(x) = \cdots = \alpha_{m_A}(x) = 0 \) in model (1)?” To estimate the functions, Brumback and Rice (1998) used the correspondence between penalized regression and mixed-effects models to extend the smoothing spline model (Wahba, 1990) for individual curves. Ramsay and Silverman (2005) suggested a penalized least squares approach with regularized basis expansions. The basis functions that are commonly used are Fourier series or B-spline functions, which allow a continuous control over smoothness while still permit as much high frequency detail in the model as the functional data require. Regarding the hypothesis tests in functional ANOVA, Faraway (1997) and Zhang and Chen (2007) proposed \( L^2 \)-norm-based test while Shen and Faraway (2004) discussed \( F \)-type test. Cuevas et al. (2004) derived the random expression of their test statistic for a \( L^2 \)-norm-based test, and used a parametric bootstrap method to approximate the null distribution. Zhang and Liang (2014) proposed to globalize the point-wise \( F \)-test suggested by Ramsay and Silverman (2005).

Compared to its frequentist peer, Bayesian functional ANOVA has been much less studied. Kaufman and Sain (2010) introduced a Gaussian process ANOVA modeling approach under Bayesian framework, where Gaussian process distributions are assigned to each batch of functional effects as priors, and Markov chain Monte Carlo (MCMC) algorithms are used for posterior sampling. They emphasized graphical summaries based on the posterior distribution of model-based analogues of traditional ANOVA decompositions of variance. In the spirit of Kaufman and Sain, Kang and Cressie (2013) proposed a spatial ANOVA model, where spatial priors are assigned for the functional effects, to analyze regional climate-change projections. Both approaches, however, are only able to deal with Gaussian functional data, and the MCMC algorithms are slow and not easy to be implemented for a different dataset.

In this work, we present a general and efficient Bayesian modeling approach to conducting ANOVA for a variety of (both Gaussian and non-Gaussian) functional data. A class of highly flexible Gaussian Markov random fields (GMRF) (see, e.g., Rue and Held, 2005) are assigned...
as priors for each batch of functional effects in the model. As shown in Section 6, the GMRF priors allow for modeling various underlying functions, such as one-dimensional curves in the example of diffusion tensor imaging (DTI), two-dimensional graphical regions in the example of Apgar scores, and even the locations in a spherical coordinate system in the example of global solar radiation. To the best of our knowledge, no functional ANOVA model has been applied to analyze the functions of the spherical coordinates before.

In our approach, the resulting posterior distributions are obtained by an efficient computational tool based on integrated nested Laplace approximations (INLA) (Rue et al., 2009). INLA provides accurate and fast approximations to the posterior marginals, and thus avoids time-consuming MCMC sampling. INLA also allows for a broad range of distributions assumed for the functional data. For instance, we use the beta distribution in the DTI example and the binomial distribution in the Apgar score example. Actually, most distributions from the exponential family can be specified. Our method is very flexible in the choice of likelihoods as well as the distributions of functional effects.

To see whether or not the functional effects are statistically significant, we in tradition conduct a hypothesis test with, e.g., 

$$H_0 : \alpha_1(x) = \cdots = \alpha_m(x) = 0 \text{ for all } x \in \mathcal{X},$$

and correct the family-wise error rate. Unfortunately, it is difficult to transfer the same concept to a Bayesian hierarchical modeling framework. We therefore resort to simultaneous credible intervals and contour avoiding sets derived from the posteriors for finding the significant functional effects. When the functions of interest are the curves as in the DTI example, it is intuitive to use the simultaneous intervals, and conclude that the functional effect is significant if any part of its interval does not contain 0. When the functions are of higher dimensions as in the other examples, it is preferable to find the contour avoiding set, in which the function is nonzero with a high probability for all $x \in \mathcal{X}$. Both approaches, however, require integrating the joint posterior distribution of $[\alpha(x_1), \ldots, \alpha(x_n)]$ given $n$ observations of $x$. It is a tough job to do, considering the integration is usually of a very high dimension due to the large sample size of a typical functional dataset, as demonstrated in all our examples. Fortunately, every posterior approximation given by INLA can be viewed as a mixture of normals, and therefore the excursion method introduced by Bolin et al. (2015) can be used to efficiently estimate the simultaneous credible intervals and the contour avoiding...
Unlike the existing MCMC based methods, the proposed functional ANOVA modeling approach can be implemented by general users without a hitch. It is easy to use INLA under Linux, Windows or Macintosh environment via R interface (R Core Team, 2017). A R package, INLA, can be downloaded from www.r-inla.org for free. The excursion method for calculating the simultaneous credible intervals and the contour avoiding sets are implemented using the excursions package, which is available at cran.r-project.org/web/packages/excursions.

In the rest of the paper, we shall address our methodology by focusing on a generalized two-way functional ANOVA model, which is probably the most commonly-used one in practice. The method is readily extended to the cases with more factors. The generalized modeling framework is introduced in Section 2. The prior distributions taken on the functional effects are specified in Section 3. The posterior inference and the construction of simultaneous credible intervals and contour avoiding sets are addressed in Section 4. Simulation studies are presented in Section 5, and three real case studies are discussed in Section 6, followed by closing remarks in Section 7. All the analysis software programs and the data sets used in this paper are available in the Supplementary Material, and we hope they will help the general users adapt the programs to their own functional ANOVA models.

## 2 Generalized Two-way Functional ANOVA Models

The one-way ANOVA model (1) can be easily extended to accommodate additional categorical variables. Let us consider a two-way functional ANOVA model here. Assume that we have a two-by-two factorial design: each level of the factor A (with \( m_A \) levels) is crossed with each level of the factor B (with \( m_B \) levels). Let \( \{y_{ijk}(x), x \in \mathcal{X} \subset \mathbb{R}^d\} \) be a functional response at \( i \)th level of A and \( j \)th level of B from \( k \)th subject, for \( i = 1, \ldots, m_A, j = 1, \ldots, m_B \) and \( k = 1, \ldots, n_{ij} \). We assume that \( y_{ijk}(x) \) has a distribution from the exponential family with the following density function

\[
\pi(y_{ijk}(x)) = \exp \left[ \frac{y_{ijk}(x)\theta_{ijk}(x) - b(\theta_{ijk}(x))}{a(\psi_{ijk}(x))} + c(y_{ijk}(x), \psi_{ijk}(x)) \right],
\]

where \( \theta_{ijk}(x) \) and \( \psi_{ijk}(x) \) are canonical function and dispersion function, respectively. The
mean and variance are given by
\[
\mu_{ijk}(x) = E(y_{ijk}(x)) = b'(\theta_{ijk}(x)) \quad \text{and} \quad \text{Var}(y_{ijk}(x)) = b''(\theta_{ijk}(x)) a(\psi_{ijk}(x)),
\]
where \(b'(\theta)\) and \(b''(\theta)\) are the first two derivatives of \(b(\theta)\) with respect to \(\theta\). We further denote the grand mean function by \(\mu\), the main effect of \(A\) at \(i\)th level by \(\alpha_i\), the main effect of \(B\) at \(j\)th level by \(\beta_j\), and their interaction effect by \(\gamma_{ij}\). Then, the mean response function \(\mu_{ijk}(x)\) is partitioned into
\[
g(\mu_{ijk}(x)) = \mu(x) + \alpha_i(x) + \beta_j(x) + \gamma_{ij}(x),
\]
where \(g\) is the link function used to associate the mean response with the two-way ANOVA model. For identifiability, we choose to restrict the batches of functions \(\alpha_i, \beta_j\) and \(\gamma_{ij}\) as follows
\[
\alpha_{m_A}(x) = 0, \quad \beta_{m_B}(x) = 0, \quad \gamma_{m_A,j}(x) = 0, \quad \gamma_{im,B}(x) = 0,
\]
for \(x \in X\). The constraints in (3) make \(\mu\) become the (transformed) mean response function at \(m_A\)th level of \(A\) and \(m_B\)th level of \(B\), and the main effect and interaction functions represent the deviations of other levels from this ‘baseline’ level.

We here explicitly write out two generalized functional ANOVA models and take them as example. Suppose the functions are observed at locations \(x_1, \ldots, x_n\). We then adopt the following notations:
\[
y_{ijk} = (y_{ijk}(x_1), \ldots, y_{ijk}(x_n))^\top, \quad \mu = (\mu(x_1), \ldots, \mu(x_n))^\top, \quad \alpha_i = (\alpha_i(x_1), \ldots, \alpha_i(x_n))^\top, \quad \beta_j = (\beta_j(x_1), \ldots, \beta_j(x_n))^\top \quad \text{and} \quad \gamma_{ij} = (\gamma_{ij}(x_1), \ldots, \gamma_{ij}(x_n))^\top.
\]
When each observation is assumed to follow a normal distribution, the two-way functional ANOVA model is given by
\[
y_{ijk} \mid \mu_{ij}, \theta_e \sim N(\mu_{ij}, \Sigma_{\theta_e}), \quad \mu_{ij} = \mu + \alpha_i + \beta_j + \gamma_{ij},
\]
where \(y_{ijk}\) follows a multivariate normal distribution with mean vector \(\mu_{ij}\) and covariance matrix \(\Sigma_{\theta_e}\) that depends on a set of parameters \(\theta_e\). The link function in (2) is the identity link in this Gaussian case. When each observation is binary and assumed to follow a Bernoulli distribution, the functional ANOVA model can be written as
\[
y_{ijk}(x_\ell) \mid \mu_{ij}(x_\ell) \sim \text{Bin}(1, \mu_{ij}(x_\ell)),
\]
\[
\text{logit}(\mu_{ij}(x_\ell)) = \mu(x_\ell) + \alpha_i(x_\ell) + \beta_j(x_\ell) + \gamma_{ij}(x_\ell),
\]
for $\ell = 1, \ldots, n$, where $Bin(n, \mu)$ denotes the binomial distribution with $n$ trials and mean $\mu$, and $\text{logit}(\mu) = \log(\mu/(1 - \mu))$ is the link function used in this case. Note that both models are subject to the linear constraints in (3).

In practice, there are at least three challenges to fit the generalized functional ANOVA models, such as models (4) and (5), under Bayesian framework. First, we need to appropriately model functional effects, which means the priors taken on them should be able to impose sufficient smoothness to remove noise while being flexible enough to work for a variety of $\mathcal{X}$ domains. The second challenge is computational. The functional data are often big and there are many functions to estimate in the functional ANOVA models. For example, in model (4) the sample size is $nm_A m_B$ if it is a balanced design, and we need to estimate totally $(m_A + m_B + m_A m_B)$ functions. Those numbers can grow fast as we consider more factors. Moreover, the computational issue becomes a lot worse when the functional response is non-Gaussian as in model (5). The third challenge comes from making simultaneous inference on the functional effects. It is often desirable to simultaneously test the functional effects to see if they are significant or not. Such tests are difficult to be conducted from both frequentist and Bayesian perspectives. In this work we attempt to address those challenges by using a novel Bayesian modeling approach as described below.

3 Priors on Functional Effects

To make Bayesian inference on model (4), we need to specify prior distributions for the functional effects $\mu$, $\alpha_i$, $\beta_j$ and $\gamma_{ij}$, and their hyperparameters. We assume each batch of functions to be independent of the other batches and assign each batch its own set of hyperparameters. The priors we choose for the functions are GMRFs, a class of flexible Gaussian processes that have been extensively used in a variety of applications (e.g., Rue and Held, 2005; Yue and Wang, 2014).

A GMRF is a Gaussian random vector $\mathbf{f} = (f_1, \ldots, f_n)'$ with Markov property: for some $i \neq j$, $f_i$ and $f_j$ are independent conditional on other variables $\mathbf{f}_{-ij}$. It is defined over a set of discrete indexed locations connected by a graph labelled by $\mathcal{G}$. We say $\mathbf{f}$ is a GMRF with
respect to $\mathcal{G}$ if its density function has the following form

$$
\pi(f) \propto \lvert Q_\theta \rvert_+^{1/2} \exp \left( -\frac{1}{2} f'Q_\theta f \right),
$$

(6)

where $Q_\theta$ is the precision matrix that depends on a set of parameters $\theta$, and $\lvert Q_\theta \rvert_+$ is the product of non-zero eigenvalues of $Q_\theta$. The Markov property in $f$ is conveniently encoded in matrix $Q_\theta$: $Q_\theta[i,j] = 0$ if and only if $f_i$ and $f_j$ are conditionally independent. In most cases only $O(n)$ of the $n^2$ entries of $Q_\theta$ are not zeroes, making $Q_\theta$ a highly sparse matrix. This allows for a fast Cholesky decomposition of $Q_\theta$ as $LL'$, where $L$ is a lower triangular matrix inheriting sparseness from $Q_\theta$. Therefore, only non-zero terms in $L$ are computed and the nodes can be reordered to decrease the number of the non-zero terms. The typical cost of this decomposition is $O(n)$ for one dimension, $O(n^{3/2})$ for two dimensions and $O(n^2)$ for three dimensions. Using the Cholesky triangle, it is easy to produce random samples from a GMRF, and compute log-density of (6) and marginal variances. See Rue and Held (2005) for more technical details. In the following sections, we briefly describe a few GMRF models that are used to analyze the real functional datasets in this paper.

### 3.1 Random walk models

To estimate one-dimensional effect functions, we use so-called second-order random walk (RW2) model. It is constructed by the following independent Gaussian increments:

$$
f_i - 2f_{i+1} + f_{i+2} \sim N(0, \tau^{-1}),
$$

where $\tau$ is the precision (inverse of variance) parameter. The resulting density of $f$ can be shown to have form (6) with $Q_\theta = \tau R$, where $R$ is the sparse structure matrix reflecting the Markov property of the model. Note that $R$ has a rank of $n - 2$, so the RW2 model has an improper Gaussian density. It can also be viewed as a discretized version of cubic smoothing splines (e.g., Yue et al., 2012).

The RW2 model can be extended to estimating two-dimensional functions by defining $\mathcal{G}$ on a regular lattice. The full conditional distributions for the nodes in the interior of the lattice are Gaussian with mean and precision given by

$$
E(f_{ij} \mid f_{-ij}) = \frac{1}{20} \begin{pmatrix}
8 & 2 & 1 \\
2 & 8 & 2 \\
1 & 2 & 8
\end{pmatrix},
$$

$$
\text{Prec} \left( f_{ij} \mid f_{-ij} \right) = 20\tau,
$$

(7)
where the locations denoted by ‘•’ represent the neighbors that \( f_{ij} \) depends on, and the number in front of each grid denotes the weight given to the corresponding ‘•’ locations. Note that we need to apply necessary boundary corrections to (7) to fix rank deficiency issue (see Rue and Held, 2005, Sec. 3.4.2). It can be proved that this two-dimensional random walk (RW2D) model has density of form (6) and its \( Q_\theta \) has a rank of \( n - 3 \). Yue and Speckman (2010) showed that the RW2D model is closely related to the thin-plate spline model (e.g., Wahba, 1990).

An important type of spatial data are so-called areal data, which are assumed to be the realizations from a function of geographic regions (e.g., the states of the United States) with adjacency information. For the areal data we often define region \( i \) and \( j \) are neighbors if they share a common border, and consider their Gaussian increments \( f_i - f_j \sim N(0, (w_{ij} \tau)^{-1}) \), where \( w_{ij} \) are positive and symmetric weights. We can let \( w_{ij} = 1 \) if region \( i \) depends on its neighbors equally. Otherwise, let \( w_{ij} \) be, for instance, the inverse Euclidean distance between region centroids. The resulting full conditional distribution of \( f_i \) is

\[
 f_i \mid f_{-i}, \tau \sim N \left( \frac{\sum_{j \sim i} w_{ij} f_j}{w_{i+}}, \frac{1}{\tau w_{i+}} \right),
\]

where \( i \sim j \) denotes the set of all unordered pairs of neighbors, and \( w_{i+} = \sum_{j \sim i} w_{ij} \) is the summation over neighbors of region \( i \). We can prove that the density of \( f \) has form (6) with

\[
 Q_\theta[i, j] = \tau \begin{cases} 
 w_{i+} & \text{if } i = j, \\
 -w_{ij} & \text{if } i \sim j, \\
 0 & \text{otherwise}.
\end{cases}
\]

Since the sum of each row is zero, \( Q_\theta \) has rank of \( n - 1 \). We here term (8) as Besag model because it is closely related to the intrinsic autoregressive model introduced by Besag and Kooperberg (1995).

### 3.2 SPDE models

The random walk models are discrete indexed in nature and thus work best for the data on regularly-spaced locations. For the observations measured at irregularly-spaced locations, a good candidate is the class of Matérn Gaussian fields, which have been extensively used in
spatial statistics due to its flexible covariance function between locations \( u, v \in \mathbb{R}^2 \)

\[
\text{Cov}(u, v) = \frac{\sigma^2}{2^{\nu-1}\Gamma(\nu)}(\kappa \|u - v\|)^\nu K_\nu(\kappa \|u - v\|),
\]

where \( K_\nu(\cdot) \) is the modified Bessel function of the second kind with order \( \nu > 0 \), \( \Gamma(\cdot) \) is the Gamma function, \( \nu \) is the smoothness, \( \kappa > 0 \) is the spatial scale, and \( \sigma^2 > 0 \) is the variance.

While a Matérn field is not computationally feasible for large data sets because its covariance matrix is completely dense and therefore difficult to invert, Lindgren et al. (2011) derived an explicit GMRF representation for Matérn Gaussian fields by solving the stochastic partial differential equation (SPDE) given by

\[
(\kappa^2 - \Delta)^{\alpha/2} [\tau f(x)] = \mathcal{W}(x), \tag{9}
\]

where \( \Delta = \sum_{i=1}^d \partial^2 / \partial x_i^2 \) is the \( d \)-dimensional Laplacian operator, \( \kappa > 0 \) is the spatial scale, \( \alpha > 0 \) controls the smoothness of the realizations, \( \tau > 0 \) controls the variance, and \( \mathcal{W} \) is the spatial Gaussian white noise. The link to the Matérn smoothness \( \nu \) and variance \( \sigma^2 \) is \( \nu = \alpha - d/2 \) and \( \sigma^2 = \Gamma(\nu)(\Gamma(\alpha)(4\pi)^{d/2} \kappa^{2\nu} \tau^2)^{-1} \). A measure of the spatial range can be empirically derived as \( \sqrt{8\nu / \kappa} \). Spectral theory shows that an integer \( \alpha \) must be chosen to obtain a Markov field. We thus let \( \alpha = 2 \), resulting in \( \nu = 1 \) for the smoothness of a two-dimensional field. Lindgren et al. solve (9) using finite element method: they first approximate \( f(x) \) with piecewise linear basis expansion defined on a triangular mesh, and then turn (9) into a system of linear equations to derive a GMRF solution with density of form (6) based on equality in distribution criterion. Given a triangulation the resulting SPDE model is the best piecewise linear approximation to the continuous solution to (9) (Lindgren et al., 2011).

The SPDE models are ideal for functional ANOVA when the data can be taken as the realizations of a spatial function. They provide fast computation and accurate estimation for a variety of spatial functions, whose locations can be either regularly spaced or irregularly spaced, and domains are in one-dimensional, two-dimensional, or even three-dimensional spherical spaces. They are also equipped with the flexibility of being extended for the functions that are non-stationary (Yue et al., 2014; Bolin and Lindgren, 2011), multivariate (Hu et al., 2013) and spatial-temporal (Cameletti et al., 2013).

Statistica Sinica: Newly accepted Paper
(accepted version subject to English editing)
3.3 Hyperpriors

For the random walk models there is only one hyperparameter $\tau$, which is the precision parameter of the Gaussian increments used to build the models. The prior on $\tau$ is often selected in an ad-hoc and subjective manner, i.e., a diffuse gamma prior, and the same hyperprior is often taken for different random walk models assigned for different effect functions in one functional ANOVA model. This is a rather important and delicate issue because the value of $\tau$ controls the smoothness of the effect function and a fixed hyperprior on $\tau$ does not have the same interpretation for different effect functions. Sørbye and Rue (2014) proposed to scale the models in a way that the $\tau$s in different models have a similar interpretation, making it more reasonable to take the same prior on $\tau$ across those models. More specifically, they consider marginal variances of $f$ given by the diagonal entries of the generalized inverse matrix $Q^{-} = \tau^{-1}R^{-}$, denoted by $\sigma^2(f_i)/\tau$ for $i = 1, \ldots, n$. To characterize the level of the marginal variances, the generalized variance of $f$ is defined to be the geometric mean

$$
\sigma_{GV}^2(f) = \exp \left( \frac{1}{n} \sum_{i=1}^{n} \log (\sigma^2(f_i)) \right).
$$

Then, the random walk models are scaled such that $\sigma_{GV}^2(f) = 1$, which implies that the precision parameters of different models have similar interpretation. The hyperpriors for scaled models will also be invariant to the shape and size of the graph for a specific model and to different scalings of covariates (Sørbye and Rue, 2014).

For SPDE models, there are two hyperparameters $\kappa$ (spatial scale) and $\tau$ (precision). Since both parameters influence the marginal variances of the resulting field, it is more reasonable to model the parameters using the standard deviation $\sigma$ and range $\rho$. Specifically, we let $\log \delta = \log \delta_0 + \theta_1$ and $\log \rho = \log \rho_0 + \theta_2$, where $\delta_0$ and $\rho_0$ are baseline standard deviation and range values. Based on the explicit mapping between $(\tau, \kappa)$ and $(\sigma, \rho)$, we may have the parameterization $\log \tau = \log \tau_0 - \theta_1 + \nu \theta_2$ and $\log \kappa = \log \kappa_0 - \theta_2$, where

$$
\log \kappa_0 = \log(8\nu)/2 - \log \rho_0,
$$

$$
\log \tau_0 = \frac{1}{2} \log \left( \frac{\Gamma(\nu)}{\Gamma(\alpha)(4\pi)^{d/2}} \right) - \log \sigma_0 - \nu \log \kappa_0,
$$

and $\theta_1$ and $\theta_2$ are assigned a joint normal prior distribution. The hyperparameters are chosen heuristically to suit the specific situation. See Lindgren and Rue (2015) for more details.
4 Posterior Inference

Let's continue to take model (4) for example. The joint posterior distribution of this generalized two-way functional ANOVA model is given by

\[ \pi(\mu, \alpha_i, \beta_j, \gamma_{ij}, \theta | y) \propto \prod_{ijk} \pi(y_{ijk} | \mu, \alpha_i, \beta_j, \gamma_{ij}, \theta) \]

subject to the linear constraints defined in (3). Here \( \pi(y_{ijk} | \cdot) \) is the likelihood function from exponential family; \( \pi(\mu | \cdot) \), \( \pi(\alpha_i | \cdot) \), \( \pi(\beta_j | \cdot) \) and \( \pi(\gamma_{ij} | \cdot) \) are the GMRF priors taken on the effect functions; the remaining \( \pi(\cdot) \) functions denote the hyperpriors. The standard MCMC approach has been proposed by Kaufman and Sain (2010) to fit a similar model but using Gaussian process priors on the effect functions. However, due to the model complexity and large data size, the MCMC simulation procedure is slow and often has mixing problems.

We here use an approximate Bayesian inference tool based on integrated nested Laplace approximations (INLA) introduced by Rue et al. (2009). The main benefit of using INLA is computational: where MCMC algorithms need hours or days to run, the approximations provide more precise estimates in seconds or minutes. It can be used to fit a large class of latent Gaussian models, of which model (10) is a special case. The asymptotic properties of INLA are given in Section 4 of Rue et al. (2009). Below we briefly describe how we use INLA to approximate the posterior distributions of the functional ANOVA model in (10).

4.1 INLA methodology

Let \( y = (y'_{111}, \ldots, y'_{11n_1}, \ldots, y'_{m_Am_Bm_Am_B})' \) denote a \( n_y \) dimensional vector of the response values, \( f = (\mu', \alpha'_1, \ldots, \alpha'_{m_A}, \beta'_1, \ldots, \beta'_{m_B}, \gamma'_{11}, \ldots, \gamma'_{m_Am_B})' \) a \( n_f \) dimensional vector of the functional effect parameters, and \( \theta = (\theta'_{\epsilon}, \theta'_\mu, \theta'_{\alpha}, \theta'_{\beta}, \theta'_{\gamma})' \) a \( n_\theta \) dimensional vector of the hyperparameters. Since the GMRF priors are taken on all the effect functions, \( f \) becomes another GMRF of form (6) with precision matrix \( Q_\theta \). This \( Q_\theta \) is a large but sparse block diagonal matrix, in which the diagonal elements are the precision matrices of all effect
functions. Then, the joint posterior distribution in (10) can be written as

$$
\pi(f, \theta | y) \propto \pi(\theta) \pi(f | \theta) \prod_{i=1}^{n_y} \pi(y_i | f_i, \theta)
$$

$$
\propto \pi(\theta) |Q_\theta|^{n_f/2} \exp \left[ -\frac{1}{2} f'Q_\theta f + \sum_{i=1}^{n_y} \log \pi(y_i | f_i, \theta) \right],
$$

and the posterior marginals of interest can be derived by

$$
\pi(f_i | y) = \int \pi(f_i | \theta, y) \pi(\theta | y) d\theta, \quad i = 1, \ldots, n_f,
$$

$$
\pi(\theta_j | y) = \int \pi(\theta | y) d\theta_{-j}, \quad j = 1, \ldots, n_\theta.
$$

(11)

There are three stages in the implementation of INLA method: firstly propose an approximation $\tilde{\pi}(\theta | y)$ to the joint posterior of the hyperparameters $\pi(\theta | y)$; secondly propose an approximation $\tilde{\pi}(f_i | \theta, y)$ to the marginals of the conditional distribution of $f_i$ given the data and the hyperparameters $\pi(f_i | \theta, y)$; finally explore $\tilde{\pi}(\theta | y)$ on a grid and use it to numerically integrate out $\theta$ in (11).

To approximate $\pi(\theta | y)$, we use the following Laplace approximation

$$
\tilde{\pi}(\theta | y) \propto \frac{\pi(f, \theta, y)}{\tilde{\pi}_G(f | \theta, y)} \bigg|_{f = f^*(\theta)},
$$

(12)

where $\tilde{\pi}_G(f | \theta, y)$ is the Gaussian approximation to $\pi(f | \theta, y)$, obtained by matching the modal configuration and the curvature at the mode $f^*(\theta)$. Note that expression (12) yields the exact posterior of $\theta$ if the likelihood is Gaussian. Since $\tilde{\pi}(\theta | y)$ is only used to integrate out uncertainty in $\theta$ when approximating $\pi(f_i | y)$, there is no need of a detailed exploration of this density, as long as we are able to select good evaluation points for the numerical integration. Rue et al. (2009) propose two different exploration schemes depending on the number of hyperparameters. For simplicity we assume that $\theta = (\theta_1, \ldots, \theta_{n_\theta}) \in \mathbb{R}^{n_\theta}$ and reparameterize $\theta$-space to make the density more regular as follows. First, find the mode $\theta^*$ of $\tilde{\pi}(\theta | y)$ and compute the negative Hessian matrix $H$ at the modal configuration. Then, we standardize $\theta$ to obtain a new variable $z = (V \Lambda^{1/2})^{-1}(\theta - \theta^*)$, where $H^{-1} = V \Lambda V'$ being the eigen-decomposition. When the dimension of $\theta$ is small ($n_\theta \leq 5$), the $z$-parametrization is used to build a grid covering the bulk of the probability mass of $\tilde{\pi}(\theta | y)$. When $n_\theta$ is a moderate number, a so-called CCD integration is used, where some ‘points’ in the
$n_\theta$-dimensional space are found to approximate the unknown function with a second order surface. It requires much less computation and is still able to capture variability in $\theta$ space if our purpose is to make inference on $\pi(f_i | y)$ only.

To approximate $\pi(\theta_j | y)$ we use the density points that have already been evaluated in the grid exploration of $\tilde{\pi}(\theta | y)$ to construct an interpolation, based on which the marginals are computed with numerical integration. The so-called asymmetric Gaussian interpolation is used to correct the Gaussian approximation for possible skewness in $\pi(\theta_j | y)$. However, the multi-dimensional numerical integration becomes unstable when fitting models with higher number of hyperparameters, resulting in approximated posterior marginals densities with undesirable spikes. To relieve this issue, Martins et al. (2013) proposed a new integration-free algorithm, where $\tilde{\pi}(\theta_j | y)$ is directly approximated by a mixture of Gaussian distributions. It gives sensible results with almost no extra computation time.

The simplest way to approximate $\pi(f_i | \theta, y)$ is by using the Gaussian approximation $\tilde{\pi}_G(f_i | \theta, y)$, which can be easily obtained from $\tilde{\pi}_G(f | \theta, y)$ that has already been computed in evaluating (12). This approximation, however, could yield errors due to the lack of skewness. It can be largely improved by doing a Laplace approximation again

$$
\pi_{LA}(f_i | \theta, y) \propto \frac{\pi(f, \theta, y)}{\tilde{\pi}_{GG}(f_{-i} | f_i, \theta, y)} |_{f_{-i} = f_{-i}^*(f_i, \theta)}, \quad (13)
$$

where $\tilde{\pi}_{GG}$ is the Gaussian approximation to the full conditional of $f_{-i}$ and $f_{-i}^*(f_i, \theta)$ is the modal configuration. Unfortunately, $\tilde{\pi}_{GG}$ must be recomputed for each $f_i$, making this approximation too expensive. Rue et al. (2009), therefore, propose two modifications to expression (13) for making it computationally feasible. A third option is called simplified Laplace approximation, which is achieved by doing a third-order Taylor expansion on the numerator and denominator of (13), and thus corrects the Gaussian approximation for location and skewness with a much lower cost (see Rue et al., 2009, for details)

4.2 Identification of significant functional effects

4.2.1 Contour avoiding set

Let $h(x)$, $x \in \mathcal{X} \subset \mathbb{R}^d$, denote certain effect function in a functional ANOVA model. It is of great interest to test the hypothesis $H_0 : h(x) \neq 0$ for all $x \in \mathcal{X}$, in order to find out
whether or not the functional effect is statistically significant. From a Bayesian point of view, we need to find a set of \( x \) such that \( h(x) \neq 0 \) with a posterior probability \( 1 - \alpha \) for all \( x \) in that set. To define this set, we need a few definitions regarding excursion and contour uncertainty as given by Bolin and Lindgren (2015). The positive excursion set of \( h(x) \) is defined by \( A^+(h) = \{ x \in \mathcal{X}; h(x) > 0 \} \). The negative excursion set is similarly defined by \( A^-(h) = \{ x \in \mathcal{X}; h(x) < 0 \} \). We then define the pair of joint contour excursion sets with probability \( 1 - \alpha \) to be

\[
(M^+_\alpha(h), M^-_\alpha(h)) = \arg \max_{(D^+, D^-)} \{|D^- \cap D^+| : P(D^- \subseteq A^-(h), D^+ \subseteq A^+(h)) \geq 1 - \alpha\},
\]

where the sets \((D^+, D^-)\) are open. The union of these two sets \( E_\alpha(h) = M^+_\alpha(h) \cup M^-_\alpha(h) \) is termed as level-zero contour avoiding set, which is the largest set such that for all \( x \) in that set the effect function \( h(x) \) is different from zero with probability \( 1 - \alpha \). Unfortunately, we will not be able to see other smaller sets satisfying the requirement if only \( E_\alpha(h) \) is reported. Also, the set \( E_\alpha(h) \) does not provide any information about the locations not contained in the set. We hence introduce a level-zero contour avoiding function defined as \( F(x) = \sup\{1 - \alpha; x \in E_\alpha\} \). It is a graphical tool that is similar to \( p \)-values, i.e., the marginal probabilities of exceeding the level, but can be interpreted simultaneously.

We now briefly describe the procedures of computing the contour avoiding set, and refer readers to Bolin and Lindgren (2015) for details. There are two main problems in the computations. The first is integration: we must calculate probability \( P(D^- \subseteq A^-(h), D^+ \subseteq A^+(h)) \) for the pair of sets \((D^+, D^-)\). The second is shape optimization: find the largest region satisfying the required probability constraint. In practice the integration will be computationally intensive when the dimension of \( h = (h(x_1), \ldots, h(x_n))^\prime \) is large (which is usually the case in functional ANOVA). Therefore, we use a method based on a parametric family for the contour sets in combination with a sequential integration for calculating the probabilities. Assume that \( h \) is Gaussian and \( D(\rho) \) is a parametric family for the possible excursion sets such that \( D(\rho_1) \supset D(\rho_2) \) if \( \rho_1 < \rho_2 \). The following strategy is then used to calculate \( E_\alpha(h) \).

First, find the reordering given by the order that the nodes are added to \( D(\rho) \) when \( \rho \) is increased. Second, sequentially add nodes to \( D \) according to the ordering given above and update probability \( P(D^- \subseteq A^-(h), D^+ \subseteq A^+(h)) \) in each step. Third, stop as soon as the probability falls below \( 1 - \alpha \), and then \( E_\alpha(h) \) is given by the last set \( D \) for which the
probability is greater than equal $1 - \alpha$. We obtain $F(x)$ by letting $\alpha = 1$ and saving the probabilities in each step. The parametric families are based on the marginal quantiles of $h(x)$, which can be easily calculated using the marginal posterior distributions. The sequential integration is greatly facilitated by the fact that $h$ is a sparse GMRF and can be viewed as a non-homogeneous auto-regressive process defined backwards in the indices of $h$ (Rue and Held, 2005).

The algorithm mentioned above is in Gaussian setting, and can be extended to the latent Gaussian setting with posterior $\pi(h|y) = \int \pi(h|y, \theta)\pi(\theta|y)d\theta$, where the full conditional $\pi(h|y, \theta)$ can be non-Gaussian if the likelihood is non-Gaussian. The basic idea to estimate the non-Gaussian posterior distributions is to use Gaussian approximations of either the posterior $\pi(h|y)$ or the conditional posterior $\pi(h|y, \theta)$, which can be provided by INLA method introduced in the previous section. Given estimates of the posterior distributions, we can then compute the excursion probabilities by one of the five different methods proposed by Bolin and Lindgren (2015).

4.2.2 Simultaneous credible interval

When $h(x)$ is in one dimension (i.e., $X \subset \mathbb{R}$), it is useful to construct the credible interval to visualize the uncertainty of the estimated function. Given an $x$ a point-wise credible interval of $h(x)$ is given by $[q_{\rho/2}(x), q_{1-\rho/2}(x)]$, where $q_{\rho}(x)$ denotes the $\rho$th-quantile of the marginal posterior distribution of $f(x)$. The quantiles can be easily computed by INLA because the marginal posterior distributions are approximated as one-dimensional Gaussian mixtures. However, to identify the significance of this functional effect we need a simultaneous credible interval, inside which $f(x)$ is with probability $1 - \rho$ for all $x$. It can be constructed by finding a value of $\eta$ such that $P(q_{\eta}(x) < h(x) < q_{1-\eta}(x), x \in X | y) = 1 - \rho$. Finding such an $\eta$ requires to integrate the joint posterior distribution of $h$ given $n$ observations of $x$, which is often computationally intensive. Fortunately, one can find this simultaneous credible interval using the method of estimating credible intervals for Gaussian mixtures in Bolin et al. (2015). It is based on the sequential integration method for Gaussian integrals that is described above. We therefor skip the description of the method here.
5 Simulation

We conduct a simulation study to evaluate the proposed method. We consider an one-way generalized ANOVA framework, where the mean response function is given by

\[ \mu_{ik}(x) = g^{-1}[\mu(x) + \alpha_i(x)], \quad x \in \mathcal{X}, \]  

\[(14)\]

for \( i = 1, \ldots, m_A \) and \( k = 1, \ldots, n \). For simplicity we let the main effect have only two levels, i.e., \( m_A = 2 \). Therefore \( \alpha_2(x) = -\alpha_1(x) \) for any \( x \), and model (14) becomes a generalized additive model (see, e.g. Wood, 2006). Both normal and binary data are simulated. For normal data, we let error standard deviation \( \sigma = 0.5 \). Regarding binary data, we use logistic link function to compute ‘success’ probability as \( P(y_{ik} = 1 \mid x) = 1/[1 + \exp(-\mu_{ik}(x))] \), based on which the data are simulated from independent Bernoulli distributions. There are 500 data sets generated for each type of response variables.

We consider two scenarios with regard to the effect functions. In Scenario I, the effect functions are smooth curves given by

\[ \mu(x_\ell) = \sin(x_\ell), \quad \alpha_1(x_\ell) = \sin(2x_\ell)/2 \]

for \( \ell = 1, \ldots, 100 \), where \( x_\ell s \) are equally spaced within \([0, 6]\). At each level of the main effect we simulate \( n = 100 \) such curves. The RW2 priors are taken on \( \mu \) and \( \alpha_1 \) functions. In Scenario II, we consider two-dimensional effect functions given by

\[
\begin{align*}
\mu(x_1, x_2) &= \frac{0.75}{\pi \sigma_{x_1} \sigma_{x_2}} \exp \left[ -\frac{1}{\sigma_{x_1}^2} (x_1 - 0.2)^2 - \frac{1}{\sigma_{x_2}^2} (x_2 - 0.3)^2 \right] \\
&\quad + \frac{0.45}{\pi \sigma_{x_1} \sigma_{x_2}} \exp \left[ -\frac{1}{\sigma_{x_1}^2} (x_1 - 0.7)^2 - \frac{1}{\sigma_{x_2}^2} (x_2 - 0.8)^2 \right] \\
\alpha_1(x_1, x_2) &= \frac{0.75}{\pi \sigma_{x_1} \sigma_{x_2}} \exp \left[ -\frac{1}{\sigma_{x_1}^2} (x_1 - 0.5)^2 - \frac{1}{\sigma_{x_2}^2} (x_2 - 0.5)^2 \right]
\end{align*}
\]

where \( \sigma_{x_1} = 0.3 \) and \( \sigma_{x_2} = 0.4 \). Both \( x_1 \) and \( x_2 \) have 40 equally-spaced realizations within \([0, 1]\), therefore the effect functions are built on \( 40 \times 40 \) grid. At each level of the main effect we simulate \( n = 10 \) such surfaces. The RW2D priors are taken on \( \mu \) and \( \alpha_1 \) functions.

As mentioned, model (14) can be formulated as a generalized additive model (GAM). A GAM, from a frequentist point of view, is usually fitted by penalized likelihood maximization, where the model likelihood is modified by the addition of a penalty for each smooth function.
to prevent it from being overfitted. A smoothing parameter is used for each penalty to balance the fidelity to data against the smoothness of fit. In mgcv R package (Wood, 2006), the smooth functions in a GAM are represented using penalized regression splines (e.g. Wood, 2003) with the basis functions designed to be optimal for these splines. The smoothing parameter is estimated by the generalized cross validation (GCV) (e.g. Wahba, 1990). For comparison purpose, we also use mgcv to fit model (14) for both scenarios, and compare it to our method using mean squared error (MSE) of each estimated function for each simulated data set as defined below

\[
\text{MSE} = \frac{1}{m} \sum_{\ell=1}^{m} \left[ f(x_\ell) - \hat{f}(x_\ell) \right]^2,
\]

where \( f \) and \( \hat{f} \) denote the true function and its estimator (posterior mean), respectively.

The figures of the distributions of log(MSEs) provided by INLA and mgcv methods for normal and binary simulated data are given in the supplementary materials of this paper. The INLA method apparently outperforms mgcv by yielding overall smaller MSEs for both effect functions in every simulated situation. It is noteworthy that the MSEs of mgcv have more variability than those of INLA. Also, the outperformance of INLA is more significant when it is more difficult to estimate the effect function. For example, in Scenario II it is harder to estimate the grand mean function than the main effect function, and therefore INLA outperforms mgcv more in estimating the former than the latter. We believe the reason that mgcv is outperformed by INLA in the simulation study is that the penalized regression splines tend to provide too smooth fits because they use low-rank spline basis functions, which are not able to capture the varying features that may exist in the true functions.

6 Examples

In this section we present three real data examples to demonstrate how to do functional ANOVA using the proposed method. The functional data in the examples differ with respect to their response distributions (normal and non-normal), the dimensions of function domain (1D, 2D and 3D), and the number of potential factors (one-way and two-way). It shows how versatile and flexible our method is. The R code with illustration of those examples is provided in the supplementary document of this paper.
6.1 Diffusion tensor imaging

Our first example is a study of functional quantitative imaging metrics of multiple sclerosis (MS) patients over multiple clinical visits (Goldsmith et al., 2012). The MS is a common chronic demyelinating disease in white matter tracts, which is often investigated by diffusion tensor imaging (DTI) methods. The DTI is a popular quantitative magnetic resonance imaging technique that measures the three-dimensional diffusion of water molecules within tissue through the application of multiple diffusion gradients. Because water diffuses anisotropically in the white matter and isotropically elsewhere, the DTI is used to generate images of the white matter specifically. It allows us to quantitatively measure tissue integrity and thus provide information about damage to the parts of nervous system.

The data in this study consist of 100 subjects, aged between 21 and 70 years at first visit. The number of visits per subject ranged from 2 to 8; a total of 340 visits were recorded. Since we are interested in the visit effect of MS patients, we restrict our attention to the 18 subjects, who had completed 4 visits within approximately one year. For each visit the DTI scans were obtained and used to create tract profiles. The derived outcome is known as fractional anisotropy (FA), which is computed from the diffusion tensor’s eigenvalues in the image processing. It is a measure describing the degree of anisotropy of a diffusion process in a brain and has been routinely used as an index of white matter integrity. The region of our interest is the right cortico-spinal tract (RCST), which is an anatomical structure that connects the motor cortex to the brain stem. The damage to the structure may be linked with a decline in cognitive performance in MS patients (Goldsmith et al., 2012). The data set is available in refund package in R (http://cran.r-project.org/web/packages/refund/index.html).

Let $y_{ij}(x)$ denote the FA measure at trace location $x$ for $j$th subject in $i$th visit. Because it is bounded between 0 and 1, $y_{ij}(x)$ is assumed to follow a beta distribution, which is capable of flexibly modeling this type of data (Wang and Li, 2014). Being interested in the visit effect on FA profiles in the RCST region, we consider the following one-way functional ANOVA model:

$$y_{ij}(x) \mid \mu, \alpha_i, \lambda \sim \text{Beta}(p_{ij}(x), \lambda),$$
$$\logit(p_{ij}(x)) = \mu(x) + \alpha_i(x),$$
Figure 1: Results of DTI example: The posterior means (solid), point-wise credible bands (dashed) and simultaneous credible bands (solid) of main effect functions (left), and the level-zero contour avoiding functions (solid), marginal probabilities (dashed) and contour avoiding set (grey) of main effect functions (right), for Visit #1 (top), Visit #2 (middle) and Visit #3 (bottom).
for $x \in \mathcal{X} \subset \mathbb{R}$, where $Beta(\mu, \lambda)$ denotes the beta distribution with mean $\mu$ and variance $\mu(1 - \mu)/(1 + \lambda)$. The function $\mu$ is the grand mean tract profile and $\alpha_i$ is the main effect function of $i$th visit. They are associated with $p_{ij}$ via logit link. For identifiability we let $\alpha_4(x) = 0$ for any $x$. The independent RW2 priors are taken on $\mu$ and $\alpha_i$ for all $i$. A diffuse gamma prior is taken on $\lambda$.

In Figure 1 we present the results. In the left panel we show the posterior mean, point-wise credible band as well as simultaneous credible band for the main effect function of each visit. We can see that the effect function becomes flatter as the patients pay more visits. It makes sense because the last visit is modeled as baseline. In terms of its dynamic change, the main effect is more significant at the locations in the middle than those at two ends. It indicates that for MS patients the middle part of RCST may be damaged more quickly than the two end parts. In the right panel we show the joint and marginal probabilities that each main effect function is non-zero. Each gray region shows the set of locations such that the main effect function is not zero with at least 0.95 probability for all locations in that region. As we can see, the region keeps shrinking as the patients pay more visits, and the three visits have the common region between 10 and 40. It concludes that the functional effect of ‘visit’ is statistically significant.

6.2 Apgar score

There is a study on mortality and live births occurred in Brazil (http://tabnet.datasus.gov.br/cgi/sinasc/dados/nov_indice.htm#docs). It is intended to produce indicators and analysis that do not only support the planning and evaluation of actions, programs and health services, but also strengthen the use of epidemiological evidence for decision-making. The information of newborns was recorded and the data were published for the period from 1996 to 2012 by the Ministry of Health in Brazil. We here select the dataset of Paraná state in 2012 for demonstration purpose.

The response variable of our interest is the Apgar score, invented by Virginia Apgar in 1952, which is often used as a method to quickly summarize the health of newborn children. It is determined by evaluating the newborn on five simple criteria (appearance, pulse, grimace, activity, respiration) on a scale from 0 to 2, then summing up the five values thus obtained.
Scores 7 and above are generally normal, 4 to 6 fairly low, and 3 and below are regarded as critically low. To identify health status of each newborn, we use a binary response variable $y = 1$ if the score is less than 7 and $y = 0$ otherwise. In addition, we associate each score with mother’s municipality of residence to make it a functional response with a spatial domain.

Figure 2: Apgar scores of newborns: Level-zero contour avoiding functions of (a) main effect of consultation; (b) main effect of mother education level; (c) effect of interaction; and 95% level-zero avoiding set of (d) main effect of mother education level.

The explanatory variables that have potential impact on the Apgar score are weight of the newborn, gestation duration, mother education level, and number of consultations during gestation. The latter three are categorical variables with more than two categories. As for factors, we use the education level and the number of consultations. Instead of using their original categories, we make the education level a binary variable with $1 =$ higher education
and 0 otherwise, and the number of consultations with 1 = full consultations (# = 4) and 0 otherwise, for easy interpretation. Then the functional binary response is decomposed according to the main effects of these two factors and their interaction. The weight and gestation duration are taken as linear effects.

As a result, we use the following two-way functional ANOVA model

\[
y_{ijk}(x) \mid p_{ijk} \sim Bin(1, p_{ijk}(x)), \quad x \in X \subset \mathbb{R}^2
\]

\[
\logit(p_{ijk}(x)) = \phi_0 + z_{ijk} \phi_1 + z'_{2ijk} \phi_2 + \mu_{ij}(x)
\]

\[
\mu_{ij}(x) = \mu(x) + \alpha_i(x) + \beta_j(x) + \gamma_{ij}(x),
\]

for \( i = 1, 2, j = 1, 2, k = 1, \ldots, n_i \), where \( Bin(n, p) \) denotes the binomial distribution with \( n \) trials and success probability \( p \) for each trial, \( \logit(p) = \log(p/(1-p)) \), \( \phi_0 \) is the intercept, and \( \phi_1 \) and \( \phi_2 \) are linear effects of weight and gestation duration, respectively. Regarding the ANOVA structure, \( \alpha_i \) is the main effect function of the \( i \)th consultation level, \( \beta_j \) is the main effect function of \( j \)th education level, and \( \gamma_{ij} \) is their interaction. Because there are only two levels per factor, we let \( i = 1 \) represent the complete consultations, \( i = -1 \) the incomplete consultations, \( j = 1 \) the higher education, and \( j = -1 \) otherwise. Then, we have \( \alpha_i = i\alpha \), \( \beta_j = j\beta \) and \( \gamma_{ij} = ij\gamma \). This reparameterization simplifies the model as well as satisfies the constraints for identifiability. With respect to the priors we assume (independent) diffuse normal distributions on the linear effects, and the Besag models on the effect functions.

The figure of the posterior means of the grand mean function, main effect function of consultation, main effect function of education level, and their interaction function is given in the supplementary materials of this paper. Both consultation and interaction effects are spatially smoother but with smaller scale than the education level effect. Figure 2 presents the level-zero avoiding functions for the two main effects and interaction, and the 95\% level-zero avoiding set of education level effect. As we can see, there are five cities identified to have the significant effects of education level on the Apgar score. Therefore the mother with higher education tends to give birth to a normal baby in those cities. Note that neither the consultation effect nor the interaction was detected to be significant in any city.
6.3 Global solar radiation

Global irradiance data are used to investigate the possible exploitation of solar energy in different areas of the planet. The data were collected at a global spatial lattice, where the longitude ranges from -180 to 179 and the latitude from -90 to 89 (negative values are south and west; positive values are north and east), yielding totally 64,800 observations of regional averages for each month. The detailed data description can be found at NASA website (https://eosweb.larc.nasa.gov/sse/). We focus on monthly averaged insolation incident over a 22-year period (July 1983 - June 2005). Insolation is a measure of solar radiation energy received on a given surface area in a given time. It is often expressed as average irradiance in kilowatt-hours per square meter per day (kWh/(m²day)). We consider direct insolation, which is measured by a surface element perpendicular to the sunbeams at a given location on earth.

We are interested in finding areas that are suitable for installing solar thermal collectors. Because they employ only direct sunlight, the collectors should be positioned in the area, where the direct insolation is constantly high through the whole year and has no strong seasonal pattern. The direct insolation is equal to the solar constant minus the atmospheric losses due to absorption and scattering. The solar constant varies with the earth-sun distance and solar cycles, while the losses depend on the cloud cover and other impurities. We therefore consider the following model

\[ y_{ij}(x) | \mu_i, \phi_i, \sigma^2 \sim N(\mu_i(x) + \phi_i(z), \sigma^2) \]
\[ \mu_i(x) = \mu(x) + \alpha_i(x), \quad x \subset \mathbb{R}^3, \quad z \subset \mathbb{R}, \]

for \( i = 1, 2, 3, 4 \) and \( j = 1, 2, 3 \). Here \( y_{ij} \) denotes the direct insulation in \( j \)th month of \( i \)th season, \( \phi_i(z) \) denotes the effect of latitude \( z \) for each season, \( \mu(x) \) and \( \alpha_i(x) \) denote the grand mean function and the main effect function of \( i \)th season, respectively, at the three-dimensional location \( x \) on the surface of the earth. We expect \( \phi_i \) to capture the seasonal pattern in solar constant while \( \alpha_i \) in atmospheric loss. The seasons are indexed as 1 = winter, 2 = spring, 3 = summer, and 4 = fall. For identifiability we let \( \alpha_4(x) = 0 \) for any \( x \), making \( \mu(x) \) become the mean function of the fall season, and \( \alpha_i(x) \) \( (i = 1, 2, 3) \) represents the difference between \( i \)th season and the fall season. We construct SPDE priors in sphere
Figure 3: Global solar radiation: level-zero contour avoiding functions (a - c) and the functions thresholded at 95% level (d - f). The seasons are winter (a and d), spring (b and e), and summer (c and f).
space, and take them on $\mu$ and $\alpha_i$ functions. The RW2 priors are assigned for $\phi_i$ functions.

The figure of the posterior means of baseline mean function and the main effect function for each season is given in the supplementary materials of this paper. Not surprisingly, the seasonal pattern of direct insolation is more significant in winter and summer than in spring and fall, because the radiation should be the same during spring and fall. It seems that Southwest China, India, Central Africa and the west coast of South America tend to receive more direct insolation in winter, while North Africa, South Africa and Brazil in summer. Figure 3 presents the contour avoiding function and the largest region where the main effect function is not zero jointly with probability .95. This region, which includes Southwest China, North India, Midwest Brazil and a few areas in Africa, is identified with significant seasonal pattern. These plots show how atmospheric losses, which are closely related to the cloud cover, change over the seasons. After comparing the cloud maps produced by the MODIS sensors on NASA’s Terra and Aqua satellites (http://modis.gsfc.nasa.gov/), we find that over the areas in the identified region the cloud cover shows a clear seasonal pattern that is similar to the one found in our direct insolation data. Based on the results shown above, south Pacific ocean, Sahara desert, southwestern US and western Australia appear to have constantly high direct insolation and can be used for installing solar thermal collectors.

7 Closing Remarks

Functional ANOVA is a powerful tool to investigate how the underlying dynamic patterns in functional data are influenced by categorical factors and their interactions. A variety of approaches for functional ANOVA have been proposed in the past decades. Bayesian analysis with MCMC samplers, have been successfully applied for a few real case studies. However, their application has never become part of standard analyses, due to a wide range of problems in terms of convergence and computational time. Moreover, the implementation to non-Gaussian functional data or the functional data with (point-level or areal) spatial effects requires careful algorithm construction. It might often be problematic, especially, for end users who might not be experts in programming.

The aim of this paper is to illustrate how generalized functional ANOVA models can be solved using the recently proposed INLA framework, which gives fast and accurate approxi-
mations instead of sampling. The approach allows us to analyze various types of functional data (both Gaussian and non-Gaussian) with (discrete or continuous) temporal effects or (point-level or areal) spatial effects easily. Both point-wise and simultaneous credible intervals for functional effects can be obtained using the excursion method with a fairly fast and accurate computation. We are able to quantitatively analyze the contribution of each factor over various regions of the functional domain by finding contour avoiding functions at those regions. The provided R code should make such models accessible to a broader audience. In addition, the INLA library provides a much larger number of likelihood functions and latent models than we illustrate here, and thus adds its flexibility to model even more complex functional data.

Although only one-way and two-way ANOVA models are shown in the paper, the proposed methodology, however, is readily extended to the case where three or more factors are of interest. For example, let’s consider three factors denoted by A, B and C, and let $y_{ijk\ell}(x)$ denote the $\ell$th function at $i$th level of A, $j$th level of B and $k$th level of C. Assuming $y_{ijk\ell}(x)$ (given $x \in \mathcal{X} \subset \mathbb{R}^d$) follows a distribution from the exponential family with mean $\mu_{ijk}(x)$ and link function $g$, a three-way generalized functional ANOVA model can be written as

$$g(\mu_{ijk\ell}(x)) = \mu(x) + \alpha_i(x) + \beta_j(x) + \gamma_k(x) + \alpha\beta_{ij}(x) + \alpha\gamma_{ik}(x) + \beta\gamma_{jk}(x) + \alpha\beta\gamma_{ijk}(x).$$

Here $\mu$ is the grand mean function; $\alpha_i$, $\beta_j$, and $\gamma_k$ are the main effect functions; $\alpha\beta_{ij}$, $\alpha\gamma_{ik}$, and $\beta\gamma_{jk}$ are the pairwise interaction functions; $\alpha\beta\gamma_{ijk}$ is the three-factor interaction function. To estimate such a model, only minor modifications are needed for the current procedures, e.g., adding more function components and linear constraints to the INLA formula.

The main disadvantage of applying the INLA approach to functional ANOVA, like in other types of latent Gaussian models, is that its computational cost increases exponentially with the number of hyperparameters. It will take INLA a relatively long time to fit a model with moderate number (e.g., 15) of hyperparameters, due to the expensive cost of evaluating the joint density of those hyperparameters. It will be our future work to make INLA feasible for the higher-order functional ANOVA models with quite a few hyperparameters.
Supplementary Materials

In the supplementary document posted online, we demonstrate how to use \texttt{R INLA} package to perform functional ANOVA step-by-step in the real data examples given in the paper. We also present an extra example that was originally studied in Kaufman and Sain (2010), and show the additional figures that are referred to but not shown in the paper.

Acknowledgements

We are grateful to the Associate Editor and two reviewers for their valuable suggestions, which substantially improved the paper. For any questions regarding the paper and/or the \texttt{R} code, please contact the corresponding author: Xiao-Feng Wang (wangx6@ccf.org).
