## WAVELET METHODS FOR ERRATIC REGRESSION MEANS IN THE PRESENCE OF MEASUREMENT ERROR

<sup>1</sup>Peter Hall, <sup>2</sup>Spiridon Penev and <sup>1</sup>Jason Tran

<sup>1</sup>*University of Melbourne* and <sup>2</sup>*University of New South Wales, Sydney*

*Abstract:* In nonparametric regression with errors in the explanatory variable, the regression function is typically assumed to be smooth, and in particular not to have a rapidly changing derivative. Not all real-data applications have this property. When the property fails, conventional techniques, usually based on kernel methods, have unsatisfactory performance. We suggest an adaptive, wavelet-based approach, founded on the concept of explained sum of squares, and using matrix regularisation to reduce noise. This non-standard technique is used because conventional wavelet methods fail to estimate wavelet coefficients consistently in the presence of measurement error. We assume that the measurement error distribution is known. Our approach enjoys very good performance, especially when the regression function is erratic. Pronounced maxima and minima are recovered more accurately than when using conventional methods, which tend to flatten peaks and troughs. We also show that wavelet techniques have advantages when estimating conventional, smooth functions since they require less sophisticated smoothing parameter choice. That problem is particularly challenging in the setting of measurement error. A real-data example is discussed, along with a simulation study.

*Key words and phrases:* Chirp, cross-validation, deconvolution, discontinuity, errors in variables, error sum of squares, explained sum of squares, kernel methods.

**1. Introduction** This paper was initiated back in July 2013 when the second author was visiting Professor Peter Hall at The University of Melbourne as part of his special study leave. Most of the theoretical treatment was performed during this time and Peter’s contribution was instrumental to the initiation of the paper. In particular, the idea to use the explained sum of squares approach which is fundamental for this paper, was Peter’s. Since the numerical implementation, testing and simulation were challenging and time consuming, it took a while to get a manuscript that could be submitted for publication. Although theoretical and numerical results were presented at some seminars and conferences, the manuscript was never actually published until Peter’s tragic and untimely death. Jason Tran was a PhD student of Peter’s and contributed to proving the main statement of the paper by essentially simplifying some of the original assumptions. The current manuscript is a fitting tribute to Peter’s contributions to the methodology of measurement error models.

In some regression problems the explanatory variable,  $X$ , is not observed directly. Instead we know the value,  $W = X + U$ , of  $X$  corrupted by an error,  $U$ , incurred when measuring  $X$ . In this setting the observed data are pairs

$(W_i, Y_i)$  for  $1 \leq i \leq n$ , all distributed as  $(W, Y)$ , where  $Y$  denotes the response when the explanatory variable is  $X$ :

$$W = X + U, \quad Y = g(X) + V. \quad (1.1)$$

Here  $g$  represents the regression mean  $g(x) = E(Y|X = x)$ ;  $V$  represents experimental error, satisfying  $E(V|X) = 0$ ; and we wish to estimate  $g$ . There is a large and extensive literature, which we shall summarise two paragraphs below, on estimating  $g$  in this setting when that function is relatively smooth. In particular, the existing methodology typically uses smoothing methods, for example modified kernel estimators, the performance of which deteriorates as  $g$  becomes more erratic. In this paper we suggest relatively adaptive methods, using wavelet techniques and based on minimising an explained sum of squares (ESS) in errors-in-variables regression. This nonstandard technique is motivated by the difficulty of estimating wavelet coefficients in the presence of measurement error. In particular, those coefficients cannot be estimated using conventional arguments.

Our ESS approach can be used in a variety of other settings too, and in particular it is straightforward to employ for non-wavelet techniques based on orthogonal series. In the wavelet context it enjoys very good performance, particularly in cases where  $g$  is more erratic than encompassed by the standard assumption that  $g$  has several bounded derivatives. For example, if  $g$

---

PETER HALL, SPIRIDON PENEV and JASON TRAN

---

has a relatively pronounced peak or trough then our wavelet-based approach generally recovers that feature more accurately than a conventional approach.

The existing methodology referred to above dates from work of Carroll and Hall (1988) and Stefanski and Carroll (1990). An excellent introduction to the literature is given in the monograph by Carroll et al. (2006). More recent contributions include those of Delaigle, and Meister (2007), Maity and Apanasovich (2011), and Delaigle et al. (2015). The paper Delaigle et al. (2015) deals for the first time with constructing confidence bands for the regression function.

An interesting approach of constructing an estimator of the regression function  $g$  has been suggested in Comte and Taupin (2007). To avoid the unrealistic situation in the usual Nadaraya-Watson construction, whereby it is assumed that  $g$  and the density  $f_X$  of the random variable  $X$  belong to the same smoothness class, the authors relax this assumption by applying a construction of an adaptive estimator as a ratio of penalized contrast function-based estimators of the product of  $gf_X$  and of the density  $f_X$  itself. However the behaviour of their estimator is driven by the slowest rate of the two estimators and it remains unclear how optimal such estimator may be. Hence they raise the question of constructing a good estimator that is different from the Nadaraya-Watson type estimator.

We will introduce our methodology in section 2. There are, as yet, no competing approaches to constructing wavelet estimators in errors-in-variables regression. Arguably the closest existing technique has been developed in Chesneau (2010), who proposed methodology in the particular case where  $X$  is known to be uniformly distributed on a specified interval. In this special case one can use periodised wavelet functions, and both practical implementation and theoretical justification are relatively straightforward. Chesneau (2010) focuses on cases where  $g$  is relatively smooth, and in fact much of the motivation for his approach derives from the fact that it can be used readily to estimate derivatives of  $g$ , as well as of  $g$  itself. However, the context of our work is quite different; the distribution of  $X$  is unknown, and in particular is unlikely to be uniform, and the function  $g$  is relatively erratic and might not have several derivatives at all points in its support.

We should also mention the work of Gençay and Gradojevic (2009) and Malloy et. al (2010); however they analyse linear models only that are quite different from our model at (1.1). Gallegati and Ramsey (2012) present results of a Monte Carlo study of techniques suggested by Ramsay et al. (2010), again in the linear model. The articles by Van Huffel (2004) and Shklyar and Semenov (2010), on total least squares methods for errors-in-variables linear regression, are also related. The majority of deconvolution-based literature

---

PETER HALL, SPIRIDON PENEV and JASON TRAN

---

in regression does not address random errors in observing the design variables, but instead treats experimental errors arising when observing a transformation of the regression mean. This context is close to a large class of deconvolution problems in image analysis, where the design points  $X$  (typically the vertices of a regular lattice) are known but, rather than observe  $Y = g(X) + V$ , as at (1.1), we observe  $Y = (Tg)(X) + V$ , where  $Tg$  denotes a linear transformation of  $g$ . There is a vast literature about inference for that model, using wavelet or related methods, and we mention here only the relatively statistical work of Abramovich and Silverman (1998), Golden-shluger (1999), Johnstone (1999), Abramovich et al. (2000), Johnstone et al. (2004), De Canditiis and Pensky (2006), Raimondo and Stewart (2007), Pensky and Sapatinas (2009), Cavalier and Raimondo (2010) and Chesneau et al. (2010). However, since  $X$  is known in these cases then the relationship between that work and our own is not strong. There is also a literature on wavelet-based density estimation in the case of measurement error. See, for example, work of Pensky and Vidakovic (1999), who considered adaptive density estimators based on Meyer-type wavelets; Pensky (2002), who studied density estimators based on compactly supported wavelets; Pensky and Zayed (2002), who introduce methods for estimating densities of conditional distributions; Fan and Koo (2002), who treat minimax optimal properties;

Bigot and Van Bellegem (2009), who estimate the log-density so as to ensure positivity; and Lounici and Nickl (2011), who address cases where replicated data are available.

## 2. Methodology

**2.1. Overview of wavelet expansions and regression estimators** The classical monograph Daubechies (1992) can be consulted for a rigorous introduction of the wavelet theory as an important tool in approximation theory. For statistical and inferential aspects of wavelets, including software implementations in the popular **R** software, we refer to Nason (2008). The wavelet expansion of a function  $g$  is given by

$$g(u) = \sum_j \alpha_j^0 \phi_j(u) + \sum_{k=0}^{\infty} \sum_j \alpha_{jk}^0 \psi_{jk}(u), \quad (2.1)$$

where  $\phi_j(u) = \rho^{1/2} \phi(\rho u - j)$  and  $\psi_{jk}(u) = \rho_k^{1/2} \psi(\rho_k u - j)$ ;  $\phi$  and  $\psi$  denote compactly supported father and mother wavelet functions, respectively;  $\rho \geq 1$ , a positive number potentially depending on  $n$ , is sometimes called the primary resolution level (see, e.g., (Hall and Penev , 2001)); and  $\rho_k = 2^k \rho$  for positive integers  $k$ . In (2.1), and in similar formulae below,  $\sum_j$  denotes summation over all positive and negative integers  $j$ . However, since  $\varphi$  and  $\psi$  in our methodology will always be assumed to be compactly supported then all but a finite number of terms in the infinite series in (2.1) vanish. We also note that sometimes in

PETER HALL, SPIRIDON PENEV and JASON TRAN

the literature,  $j$  is used to denote the scale and  $k$  is used as a location index.

Our goal is to estimate  $g(u)$  for values of  $u$  in the compact interval  $[a, b]$  supporting  $f_X$ , and  $g$ .

Using a conventional hard thresholding rule to ensure adaptivity, one would estimate  $g$  by the function  $\hat{g}(u) = \hat{g}_{t,\rho,m}(u)$ :

$$\hat{g}(u) = \sum_j \hat{\alpha}_j \phi_j(u) + \sum_{k=0}^m \sum_j \hat{\alpha}_{jk} I(|\hat{\alpha}_{jk}| > t\hat{\sigma}_{jk}) \psi_{jk}(u), \quad (2.2)$$

where  $\hat{\alpha}_j$  and  $\hat{\alpha}_{jk}$  estimate  $\alpha_j$  and  $\alpha_{jk}$ , respectively;  $I(|\hat{\alpha}_{jk}| > t\hat{\sigma}_{jk}) = 1$  if  $|\hat{\alpha}_{jk}| > t\hat{\sigma}_{jk}$ , and equals 0 otherwise;  $\hat{\sigma}_{jk}$  is an estimator of the variance of  $\hat{\alpha}_{jk}$ ; and the threshold,  $t > 0$ , is a tuning parameter. Wavelet estimators are generally robust against choice of  $m$ , which is often taken to be a constant multiple of  $\log n$  and, in particular, usually is not chosen specifically from the data. The value of  $\hat{\sigma}_{jk}$  can be computed using bootstrap methods, although it is often adequate to employ an upper bound. Theoretical arguments (Donoho and Johnstone , 1994) suggest taking  $t = (C \log n)^{1/2}$  where  $C$ , for example  $C = 2$ , is a positive constant.

We take an unconventional approach, motivated by the presence of error in measurements of the explanatory variables. Specifically, we first estimate  $\alpha_j^0$  and  $\alpha_{jk}^0$  directly, using an argument based on explained (or error) sum of squares; see section 2.3. Next we fit the model at (2.2), but with the thresholding term  $I(|\hat{\alpha}_{jk}| > t\hat{\sigma}_{jk})$  replaced by 1. Then we use matrix regularisation

to reduce noise; see section 2.4 for details. The resulting estimator,  $\hat{g}$ , is

$$\hat{g}(u) = \sum_j \hat{\alpha}_j \phi_j(u) + \sum_{k=0}^m \sum_j \hat{\alpha}_{jk} \psi_{jk}(u), \quad (2.3)$$

rather than (2.2). We have conducted numerical experiments using explicit regularisation, as at (2.2), and found that its performance is generally similar to, but on average slightly inferior to, matrix regularisation.

## 2.2. Regression estimation in the measurement error model

Recall that, in the case of regression with measurement error, the observed data pairs  $(W_i, Y_i)$ , for  $1 \leq i \leq n$ , are generated by the model at (1.1), where  $U$  denotes a measurement error,  $V$  is an experimental error and satisfies  $E(V) = 0$ , and the variables  $U, V$  and  $X$  are completely independent of one another. The distribution of  $U$  is assumed known. We stress that since this assumption seems strong, different attempts have been made in the past to alleviate it. For example, one can assume that replicated data  $W$  sampled for the same value of  $X$  is available, or that it is possible to draw separate samples from the error distribution itself. The literature on such methods is vast. Rather than trying to make a list (which in any case would be incomplete), we refer to the introductory Section 1 of the recent paper Delaigle and Hall (2016) and to the reference list therein. Perhaps surprisingly, after the introduction, the same paper demonstrates, via completely new approach,

PETER HALL, SPIRIDON PENEV and JASON TRAN

that identification in the deconvolution problem can in principle be achieved even when the distribution of  $U$  is unknown (but symmetric) and without extra data of any type. The paper Delaigle and Hall (2016) deals with density deconvolution but as the authors point out, the methodology can be extended to regression with measurement error. However, combining the non-standard assumptions of this remarkable paper with the setting of the current paper to make their procedure work without the assumption of a known distribution of the measurement error's distribution, is quite challenging and could not be discussed here. Therefore we will continue using the assumption of known distribution of  $U$  in the rest of this paper.

The methodology that we shall introduce in section 2.3 will rely on estimators  $\hat{f}_W$  and  $\hat{f}_X$  of the densities  $f_W$  and  $f_X$  of  $W$  and  $X$ , respectively. Construction of those quantities is straightforward. Indeed, since we observe data  $W_1, \dots, W_n$  then  $\hat{f}_W$  can be computed very conventionally:

$$\hat{f}_W(w) = \frac{1}{nh_1} \sum_{i=1}^n L\left(\frac{w - W_i}{h_1}\right),$$

where  $L$  is a standard univariate kernel, which we take to be a bounded, symmetric, univariate probability density.

The deconvolution kernel estimator  $\hat{f}_X(x)$  has been introduced first by Carroll and Hall (1988) and by Stefanski and Carroll (1990). Let  $K$  be a bounded, integrable function on the real line, satisfying  $\int_{-\infty}^{\infty} K(x)dx = 1$ , and

let  $K^{Ft}$  denote the Fourier transform of  $K : K^{Ft}(t) = \int_{-\infty}^{\infty} \exp(itu)K(u)du$ .

Let  $f_U^{Ft}$  be the characteristic function corresponding to the density  $f_U$  of  $U$ ,

let  $h_2 > 0$  be a bandwidth, and define

$$K_U(u) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \exp(-itu) \frac{K^{Ft}(t)}{f_U^{Ft}(t/h_2)} dt,$$

where the notation  $i$ , only when appearing in an exponent, will denote  $\sqrt{-1}$

rather than an index. The deconvolution kernel estimator of  $f_X$  is given by

$$\hat{f}_X(x) = \frac{1}{nh_2} \sum_{i=1}^n K_U \left( \frac{x - W_i}{h_2} \right)$$

for  $x \in [a, b]$ .

### 2.3. Explained sum of squares

Noting that

$$E \{g(X)|W=w\} = \frac{1}{f_W(w)} \int_a^b g(x) f_U(w-x) f_X(x) dx, \quad (2.4)$$

we deduce that if  $g$  is given by (2.1) then

$$\begin{aligned} E \{g(X)|W=w\} &= \frac{1}{f_W(w)} \left\{ \sum_j \alpha_j^0 \int_a^b \phi_j(x) f_U(w-x) f_X(x) dx \right. \\ &\quad \left. + \sum_{k=0}^{\infty} \sum_j \alpha_{jk}^0 \int_a^b \psi_{jk}(x) f_U(w-x) f_X(x) dx \right\}. \end{aligned} \quad (2.5)$$

Formula (2.5) motivates computing  $\hat{\alpha}_j$  and  $\hat{\alpha}_{jk}$  by minimising the explained sum of squares,

$$\begin{aligned} S(\alpha) &= \sum_{i=1}^n \left[ Y_i - \frac{1}{\hat{f}_W(W_i)} \left\{ \sum_j \alpha_j \int_a^b \phi_j(x) f_U(W_i-x) \hat{f}_X(x) dx \right. \right. \\ &\quad \left. \left. + \sum_{k=0}^m \sum_j \alpha_{jk} \int_a^b \psi_{jk}(x) f_U(W_i-x) \hat{f}_X(x) dx \right\} \right]^2 w_i, \end{aligned} \quad (2.6)$$

PETER HALL, SPIRIDON PENEV and JASON TRAN

where  $\hat{f}_W$  and  $\hat{f}_X$  are estimators of  $f_W$  and  $f_X$ , respectively, such as those introduced in section 2.2;  $w_i$  denotes a nonnegative weight; and  $\alpha$ , a vector of finite length  $p$ , say, denotes the concatenation of values of  $\alpha_j$  for all  $j$ , and  $\alpha_{jk}$ , the latter only for  $1 \leq k \leq m$  but for all  $j$ . The right-hand side of (2.6) becomes a little simpler, and numerically more robust, if we take  $w_i = \hat{f}_W(W_i)^2 v_i$ , where  $v_i$  is a bounded, nonnegative weight, which gives:

$$\begin{aligned} S(\alpha) &= \sum_{i=1}^n \left\{ Y_i \hat{f}_W(W_i) - \sum_j \alpha_j \int \phi_j(x) f_U(W_i - x) \hat{f}_X(x) dx \right. \\ &\quad \left. - \sum_{k=0}^m \sum_j \alpha_{jk} \int \psi_{jk}(x) f_U(W_i - x) \hat{f}_X(x) dx \right\}^2 v_i, \end{aligned} \quad (2.7)$$

Since only a finite number of values  $\alpha_j, \alpha_{jk}$  are nonzero, and those values are identified from the support of the wavelet, then, prior to regularisation, computing  $\hat{\alpha} = \operatorname{argmin}_{\alpha} S(\alpha)$  is a matter of matrix inversion.

**2.4. Regularisation** Taking each  $v_i = 1$  for simplicity, we write (2.7) as

$$S(\alpha) = \|Z - A\alpha\|^2,$$

where  $Z$  is an  $n$ -vector with components  $Y_i, \hat{f}_W(W_i)$  and  $A$ , a function of the data, is an  $n \times p$  matrix. Thus,  $A = Q_1 \Lambda Q_2^T$  where  $Q_1$  and  $Q_2$  are respectively  $n \times n$  and  $p \times p$  orthogonal matrices, and  $\Lambda$  is a diagonal matrix with components  $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_{\min(n,p)} \geq 0$  down the main diagonal. The minimum-norm value of  $\hat{\alpha} = \operatorname{argmin}_{\alpha} S(\alpha)$  is

$$\hat{\alpha} = A^- Z = Q_2 \Lambda^- Q_1^T Z \quad (2.8)$$

where  $A^-$  and  $\Lambda^-$  denote Moore-Penrose inverses and, in particular,  $\Lambda^- = D(p_1)$ , with  $p_1$  denoting the largest  $j \leq p$  such that  $\lambda_j > 0$ , and where, for  $q \leq p_1$ , we define

$$D(q) = \text{diag}(\lambda_1^{-1}, \dots, \lambda_q^{-1}, 0, \dots, 0).$$

We regularise by choosing  $q \leq p_1$  to minimise a cross-validation estimator of mean squared prediction error, and then we take

$$\hat{\alpha} = \hat{\alpha}(q) = Q_2 D(q) Q_1^T Z, \quad (2.9)$$

in place of the value at (2.8). Our estimator of  $g$  is then defined as at (2.3), although with  $\hat{\alpha}$  given by (2.9), and depends on the  $q$  chosen largest eigenvalues of  $\Lambda$ .

To construct the cross-validation criterion, let  $\hat{f}_{W,-i}$ ,  $\hat{f}_{X,-i}$  and  $\hat{g}_{-i}$  denote the versions of  $\hat{f}_W$ ,  $\hat{f}_X$  and  $\hat{g}$  computed from the dataset  $\{(W_1, Y_1), \dots, (W_n, Y_n)\}$  excluding the  $i$ th pair. Let  $\mathcal{I}$  be a subset of the set  $\{1, \dots, n\}$  for which  $\hat{f}_W(W_i)$ , or perhaps  $\hat{f}_{W,-i}(W_i)$ , is bounded above a given positive constant. Reflecting on (2.4), define

$$T(q) = \sum_{i \in \mathcal{I}} \left\{ Y_i - \frac{1}{\hat{f}_{W,-i}} \int \hat{g}_{-i}(x) f_U(W_i - x) \hat{f}_{X,-i}(x) dx \right\}^2. \quad (2.10)$$

Alternatively we could multiply the  $i$ th summand on the right-hand side of (2.10) by  $\hat{f}_{W,-i}(W_i)^2$ , and take the sum over  $i = 1, \dots, n$ . The quantity  $\hat{g}_{-i}$ , on the right-hand side of (2.10), depends on  $q$ , although this is suppressed

PETER HALL, SPIRIDON PENEV and JASON TRAN

in notation. That dependence is the source of the dependence on  $q$  of the left-hand side of (2.10). We choose  $q = \hat{q}$  to minimise  $T(q)$ . In numerical practice we have found that replacing  $\hat{f}_{W,-i}$  and  $\hat{f}_{X,-i}$  by their non leave-one-out variants,  $\hat{f}_W$  and  $\hat{f}_X$ , usually has negligible effect on results. Of course, it produces significant savings in computation time.

### 3. Computation and numerical examples

#### 3.1. Computing wavelet and kernel estimators, and tuning parameters

Our numerical experiments were performed in FORTRAN 95. We employed compactly supported wavelets from the Daubechies family, with extremal phase and highest number of vanishing moments compatible with the width of the wavelets support (see Daubechies , 1992, p. 195). A parameter  $N$  determines the length of the support for both father and mother wavelets as  $2N - 1$ . The smoothness (regularity) of these wavelets increases with  $N$ . We chose  $N = 5$  throughout. This, in our vast experience, represents a compromise between smoothness and length of the compact support for this family. Although these wavelets do not have an explicit analytic formula, they can be approximated arbitrarily accurately via some refinement schemes.

Smoothing parameters involved in the definition of  $S(\alpha)$ , at (2.6), include

the initial resolution  $\rho$  and the bandwidths  $h_1$  and  $h_2$  used to construct the density approximations  $\hat{f}_W$  and  $\hat{f}_X$ , respectively. We chose  $h_1$  using the iterative bandwidth selector proposed by Engel et al. (1994), after experimenting with other methods. Although  $h_2$  ideally should be chosen larger than  $h_1$ , we found it to be convenient, and to give good results, if we took  $h_1 = h_2$ .

Some theoretical work by Hall and Penev (2001) has been done for the choice of  $\rho$  in the setting of wavelet regression without measurement error. In principle, practical choice could be to include  $\rho$  itself also as a part of the cross-validation functional of Section 2.4 and to optimize it also with respect to  $\rho$ . A much less computationally demanding alternative is to choose  $\rho$  from a certain range of values and then to compensate for a slight inaccuracy via a choice of the value of  $q$  through the cross-validation procedure. This approach works well because the choice of  $q$  turned out to be by far the most important choice of a tuning parameter in our model and in that sense the precise choice of  $\rho$  is only of secondary importance. Using experimentation we found that  $m = 5$ , and  $\rho$  in the range from 3 to 10, gave excellent results for  $n$  between 100 and 1000 and recommend these choices in practical applications. We took  $\rho = 3$  throughout the simulations reported in section 3.2, and employed cross-validation to select  $q$ ; see (2.10).

In sections 3.2 and 3.3 the results obtained using our approach are com-

---

PETER HALL, SPIRIDON PENEV and JASON TRAN

---

pared with those found by conventional errors-in-variables regression estimator of Nadaraya-Watson type, first proposed in Fan and Truong (1993), with bandwidth chosen using the SIMEX method of Delaigle and Hall (2008). Intuitively, if the noise-to-signal ratio, or nsr, for the measurement error were small then it could simply be ignored, without having much impact on the resulting estimators. Taking the same approach when the nsr is larger, however, would be expected to cause serious damage to the fit. Our method, which takes the influence of the measurement error in its stride, should perform better in such cases, especially for more complex signals, as long as the sample size is large enough for model parameters to be estimated sufficiently accurately. To assess this hypothesis we also constructed standard kernel and wavelet estimators without acknowledging that noise is present. We found that the standard conventional wavelet estimator that simply disregards the measurement error in the input variable, performed poorly in our simulation. The empirical wavelet coefficients in this case need to be evaluated using observations on an irregular grid, and that is known to cause difficulties for the wavelet estimator (see, e.g., (Hall and Turlach , 1997; Cai and Brown , 1998)).

By now, there are some remedies for such cases, based on the second-generation wavelets (or lifting) that have performed well in empirical work. The original lifting approach of W. Sweldens was exploited in a series of papers

(see, e.g., (Claypoole et al. , 2003; Delouille et al. , 2004; Jansen et al. , 2009; Nunes et al. , 2006) and the references therein). However, the difficulties are further exacerbated in our case due to the fact that the input variables are not uniformly distributed, and that their values are observed inexactly, due to the presence of measurement error. As a result the wavelet coefficients were evaluated inaccurately, which degraded the quality of the estimated curve. For this reason we do not include results obtained using the conventional wavelet estimator.

The standard kernel regression estimator of Nadaraya-Watson type that does not acknowledge the noise  $U$  performed noticeably better, and we briefly discuss the performance of this method in our simulation comparison in section 3.2. To make the comparison as fair as possible, we employed a particularly reliable method for kernel regression, with a sophisticated tuning parameter choice also in this case. In particular, we borrowed the procedure described theoretically in Chapter 7 of the monograph by Müller (1988). We used a second-order minimum variance kernel, discussed in Chapter 5 of Müller (1988), for the estimation step, and applied cross-validation with a choice of 20 different widths, utilising routines in Chapter 12 of Müller (1988). In this way a fair comparison, described in the next section, was implemented using the following three methods: Our new wavelet technique in the pres-

---

PETER HALL, SPIRIDON PENEV and JASON TRAN

---

ence of measurement error (WAVERR), the kernel method in the presence of measurement error (KERERR), and conventional kernel regression ignoring measurement error.

**3.2. Simulation study** We took the variance of  $U$  to be 0.05, 0.10 or 0.15 times that of  $X$ ; these values represent nsr. The kernel  $K$ , in section 2.2, was the standard normal density. Sample sizes used predominantly were  $n = 300, 600$  or  $900$ , which are relatively small compared with those in conventional statistical applications of wavelets, where typically  $n = 512, 1024, 2048, 4096$  or more. We shall discuss results for smaller and larger sample sizes in text. We first report results for model 1, where  $g(x) = 5 \sin(2x) \exp(-16x^2/50)$ , and model 2, where  $g(x) = -3 \cos^2\{-x - (\pi/15)\}$  if  $x < 0$ , equals 0 if  $x = 0$ , and equals  $3 \cos^2\{x - (\pi/15)\}$  if  $x > 0$ . In particular, model 1 is particularly smooth but has increasingly small oscillations, of constant wavelength, in the tails, whereas model 2 has a marked discontinuity at the origin. In each case the distributions of  $X$  and  $V$  were both normal  $N(0, 1.5)$ , and the distribution of the measurement error,  $U$ , was Laplace.

We note that the discontinuity in model 2 could in principle be handled with kernel methods. For example, in the error-free case, if we knew that there was a discontinuity, we then estimate the discontinuity and make adjustments

to the estimator taking the discontinuity into account (see e.g., (Gijbels et al. , 1999)). The problem seems not to have been studied in the measurement error literature for the regression case until now. In any case, the essential advantage of the wavelet-based procedure we propose here in the case of estimating erratic regression means, is that the adjustment to the discontinuity happens in an automatic way.

**Remark 1.** It should be mentioned that our choice of the kernel  $K$  as the standard normal density is possible and justified in view of the choice of the measurement error model to be Laplace distributed (i.e., the error belongs to the ordinary smooth family of distributions (Fan and Truong , 1993)). It would not be possible to choose  $K$  as above if, for example, the measurement error was also normally distributed (i.e., super smooth in Fan and Truong's sense) because then the integral in the definition of the deconvolution kernel  $K_U$  would not exist if  $n$  was large enough.

□

For each combination of model and sample size above, we repeated the data generating process and the curve fitting steps 101 times for the two methods WAVERR and KERERR, and calculated the corresponding integrated squared error,

$$ISE = \int_{-2}^2 \{\hat{g}(x) - g(x)\}^2 dx,$$

---

PETER HALL, SPIRIDON PENEV and JASON TRAN

---

of the fit for each method. Quantities proportional to medians of the 101 ISE values are reported in Table 1. It can be seen from Table 1 that, in the cases  $\text{nsr} = 0.05$  and  $\text{nsr} = 0.10$ , and for each model and each sample size, the median value of ISE is less for the wavelet based estimator than for its kernel counterpart. In the setting of model 1, this is due to the fact that the wavelet estimator operates for smooth functions as though it were a kernel estimator with a kernel of slightly higher order than the actual kernel method that we employed. However, for smaller sample sizes the relationship is reversed; for example, when  $n = 150$  and  $\text{nsr} = 0.05$ , the median values of ISE for WAVERR and KERERR are respectively 4.97 and 3.98, reflecting the relatively poor performance of WAVERR for smaller sample sizes, discussed further two paragraphs below.

More importantly, the trend is also observed for model 2, where the wavelet estimator outperforms its kernel counterpart for all sample sizes and for  $\text{nsr} = 0.05$  and  $\text{nsr} = 0.10$ . The regression mean in model 2 has a jump discontinuity, and the pattern of performance in this setting reflects the known advantages of using wavelet methods in such instances. It can be shown that in this case, even when there is no measurement error, the expected value of ISE for the kernel estimator and an optimal choice of bandwidth is of size no larger than a constant multiple of  $n^{-1/2}$ , and cannot be reduced by using

Table 1: Values of  $10^3$  times the median of 101 simulated values of ISE (integrated squared error) for the WAVERR and KERERR estimators, for noise-to-signal ratios 0.05, 0.10 and 0.15 and sample sizes  $n = 150, 300, 600, 900$  and 1200 in cases where  $g$  is the smooth function in model 1, or the function with a pronounced discontinuity in model 2.

higher order kernels. (Of course, an ISE of size  $n^{-1/2}$  corresponds to a root-ISE of size  $n^{-1/4}$ .)

Further, to get a visual idea about the reasons behind the better overall performance of the wavelet-based procedure as illustrated in the table, we also present graphs of typical estimated curves when using the three estimation methods for each of the chosen sample sizes. We define as typical the fits that produced the median ISE values for the WAVEERR method out of the 101 simulated functions. Intuitively, it must be clear what stays behind the better performance of the WAVEERR method- the main reason is that as a wavelet-based procedure, WAVEERR allows one to zoom in better into discontinuities, peaks and troughs. Figure 1 illustrates an overlay of the fits when the noise-to-signal ratio was 0.05.

The relatively poor performance of the wavelet approach for relatively high nsr and small sample sizes, as seen in Table 1 when nsr = 0.15, can be seen too for sufficiently small sample sizes, smaller than those addressed by Table 1. The consistent pattern is that for each value of nsr, and each model, there is a sample size,  $n_{\text{nsr}}$  say, above which the kernel method is outperformed by the wavelet approach, and below which the kernel method gives best performance and the ratio of median ISE for the wavelet method, to median ISE for the kernel method, decreases as  $n$  increases. The value of

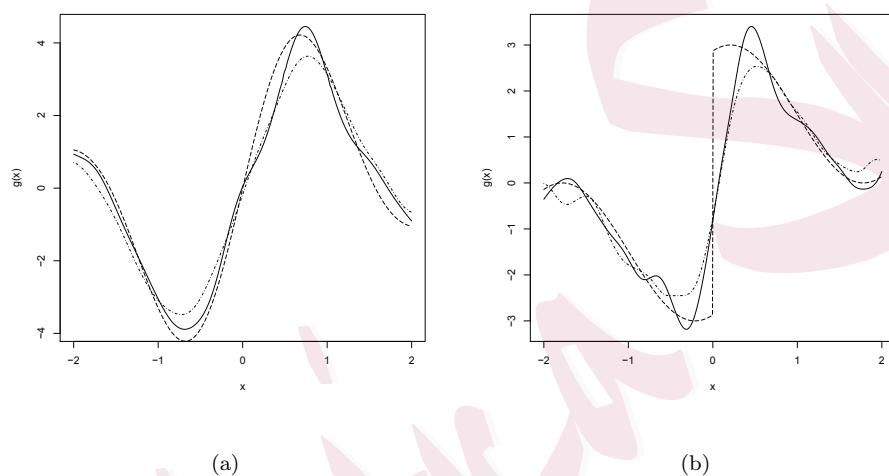

Figure 1: Left panel: Estimators of a smooth curve (model 1). Right panel: estimators of a discontinuous curve (model 2). Typical (median ISE) curves,  $n = 300$ , noise-to-signal ratio 0.05. True model: longdashed line, WAVEERR estimator: solid line, KERERR estimator: dot-dashed line.

---

PETER HALL, SPIRIDON PENEV and JASON TRAN

---

$n_{\text{nsr}}$  increases with  $\text{nsr}$ . Of course, any improvements that the wavelet approach has to offer arise partly through the qualitatively different appearance of wavelet estimators, rather than just through reduced values of integrated squared error. This is relatively straightforward to see in the context of model 2, above, where the wavelet estimator tracks the jump discontinuity relatively closely. It is more subtle, however, for relatively smooth models such as model 1. In those settings, particularly when turning points in the function  $g$  are relatively narrow, even though they have many bounded derivatives, the wavelet estimator reaches more deeply into the peak or trough.

Table 1 represented the comparison of the most worthy competitors, namely WAVERR and KERERR. In an extended version of this paper, we made a thorough comparison with the Nadaraya-Watson conventional regression method that completely ignores the measurement error (we call this method REGNOERR). The results, for the same sample sizes, and same  $\text{nsr}$ , as expected, were worse than the ones presented in Table 1 and we do not include them completely in this paper. Some numbers for the median ISE for model 2 in the case of REGNOERR are listed for comparison: when  $\text{nsr} = 0.05$  : 5.71 and 5.45 for  $n = 600$  and  $n = 900$ ; when  $\text{nsr} = 0.10$  : 8.08 and 7.91 for  $n = 600$  and  $n = 900$ ; when  $\text{nsr} = 0.15$  : 10.06 and 9.78 for  $n = 600$  and  $n = 900$ . Not only are these results worse than the related results in Table

but it also can be seen that for this method, the median ISEs virtually do not change when the sample size is increased from 600 to 900, which indicates a non-consistency of the REGNOERR method. Of course, this observation is well-known in the measurement error literature.

We have further experimented, in an extended version of this paper, with the regression function  $g(x) = 3 \sin\{2\pi(x + 0.1x^2)\}$  that has features of a chirp. Our simulations show clearly that the wavelet estimator does a much better job of reaching into peaks and troughs of the true regression mean. In this example we also assessed the performance of the standard kernel estimator when no allowance was made for measurement error. Even when  $\text{nsr} = 0.05$ , there was always an increase in median ISE if we did not allow for measurement error. Of course, improvements in performance were greater for larger values of  $\text{nsr}$ .

**3.3. Application to GDP data** Gross Domestic Product (GDP) is recorded quarterly and is prone to significant error (Fixler , 2009). It represents a sum of several (seven in the case of the USA) components, each of which is measured with error. Sources of error are discussed by Young (1994), and on web pages of the US Bureau of Economic Analysis. The average absolute values of the revisions is reported, typically with an error of about 2%. Economic theory suggests that there is a long-term association between economic activity and

---

PETER HALL, SPIRIDON PENEV and JASON TRAN

---

stock prices. Additionally, the Dow Jones Industrial Average (DJIA) is an average of the price of 30 of the largest and most widely traded US stocks, and so it should be interpretable as a noisy function of stock prices.

With this in mind we examine a scatterplot of the Dow Jones Industrial Average (DJIA) index, scaled by the factor 1000, and the seasonally adjusted US Real GDP, in trillions of 2009 US dollars. The data are available from the US Federal Reserve at <http://research.stlouisfed.org/fred2/series/>. We extracted quarterly data from January 1 1973 to January 1 2015, a sample size of 169. The year 1973 is motivated as the starting point since in that year the US decoupled completely the value of the US dollar and the gold standard. The relationship between GDP and DJIA was much less volatile prior to 1973, and so wavelet methods are not as well motivated in that time period.

Work of Young (1994) suggests taking the standard deviation,  $\sigma$ , of the Laplace distribution to equal 0.2, which we did. The fit is stable with respect to values of  $\sigma$  in the range 0.15 to 0.25. The graph in Figure 2 compares two fits, obtained using conventional deconvolution kernel and wavelet methods, respectively. Bandwidths for the conventional method were chosen using SIMEX. The parameters involved in the wavelet fit were  $\rho = 5$ ,  $m = 4$  and  $N = 5$ , and  $q$  was determined by cross-validation. Historical records, for ex-

ample during financial crises in 2002, 2003 and 2009, demonstrate sharp falls in DJIA despite the relative stability of GDP figures. These falls influenced significantly the regression means at certain GDP values. However, the conventional estimator is not able to estimate these erratic values accurately. As Figure 2 shows, the wavelet estimator adapts better.

#### 4. Theoretical properties

In this section we show that our estimator  $\hat{g}$ , for an empirically chosen set of wavelet coefficients, is consistent for  $g$  (see the main theorem below). Recall that  $[a, b]$  denotes the support of  $f_X$ , and let  $(c, d)$  be a bounded interval containing  $[a, b]$ . *Assumption 1(c)* below, will assert that  $\int_{[a,b]} |dg(x)| < \infty$  where the integral denotes the total variation of  $g$ . Let  $B_1 > 0$  denote the finite value of the latter integral. Let us put  $B_2 = \sup_{x \in [a,b]} |g(x)|$ , and, given  $B_3 > \max(B_1, B_2)$  and an integer  $m \geq 1$ , define  $\mathcal{A}_m$  to be the set of vectors  $\alpha$  of potential wavelet coefficients such that (4.1) and (4.2) hold:

$$g(x|\alpha, m) = 0 \text{ for all } x \notin [c, d], \quad (4.1)$$

$$\sup_{x \in [c,d]} |g(x|\alpha, m)| \leq B_3, \quad \int_{[c,d]} |dg(x|\alpha, m)| \leq B_3. \quad (4.2)$$

We have simplified notation by not indicating the dependence of  $\mathcal{A}_m$  on  $B_3$ .

Note from section 2 that  $\phi$  and  $\psi$  are compactly supported. We assume

PETER HALL, SPIRIDON PENEV and JASON TRAN

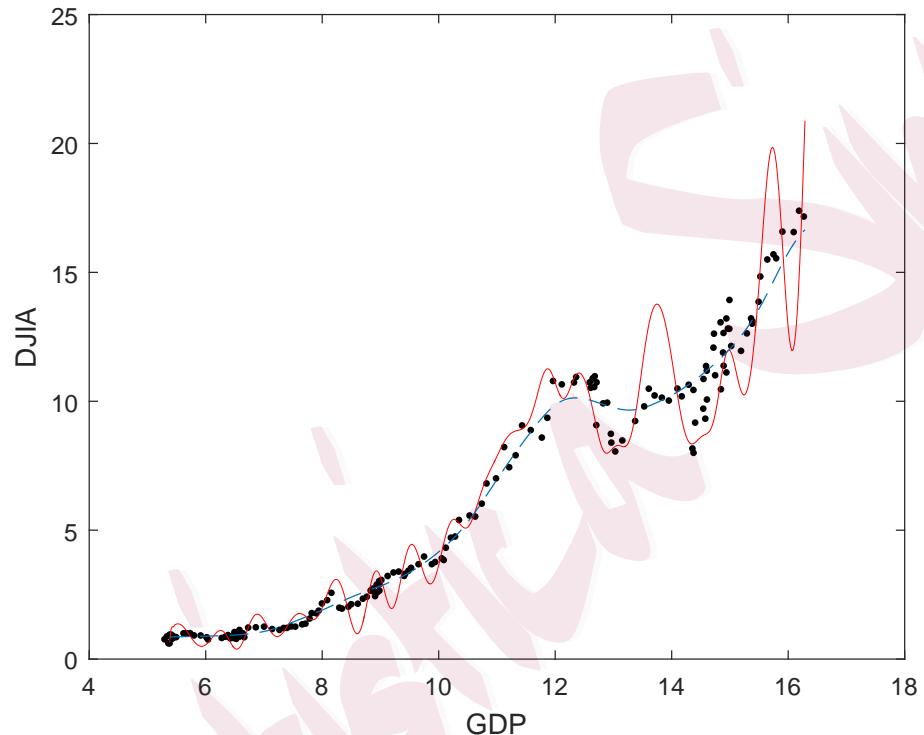

Figure 2: The black data dots are values of  $(GDP, DJIA)$  pairs, the dashed line depicts the conventional estimator KERERR of the regression mean, and the solid line shows the wavelet-based estimator WAVERR.

too that either they are Haar wavelets, or they are differentiable and hence of bounded variation. Then, if  $\alpha^0$  is taken to be the true sequence of wavelet coefficients  $\alpha_j^0$  for  $j \in \mathbb{N}$  and  $\alpha_{jk}^0$  for  $k \in \{0, \dots, m\}$ ,  $j \in \mathbb{N}$  in (2.1), conditions (4.1) and (4.2) both hold for all sufficiently large  $m$ . Therefore  $\mathcal{A}_m$  is nonempty for such  $m$ .

*Assumption A1(d)*, below, asserts that we consider only wavelet coefficient vectors that lie in  $\mathcal{A}_m$ :

-*Assumption A1*

- (a)  $f_X$  is continuous, with support equal to the compact interval  $[a, b]$ , and of bounded variation; (b)  $f_W$  is continuous and  $f_W(w) > 0$  for all  $w \in \mathbb{R}$ ;
- (c)  $g$  is of bounded variation on  $[a, b]$ ; (d) for each  $m$ , the coefficient vector  $\alpha$  used to construct  $g(x|\alpha, m)$  is constrained to lie in  $\mathcal{A}_m$ ; (e)  $f_U^{Ft}$  has at most a countable number of zeros on the real line; and (f) the distribution of  $V$  is compactly supported. □

**Remark 2.** Cohen et al. (1993) construct wavelets that can serve as an orthonormal basis strictly on a compact interval rather than on the whole real line. If one were to use such wavelets to estimate  $g$ ,  $[c, d]$  in the construction of  $\mathcal{A}_m$  can be replaced precisely by  $[a, b]$ .

**Remark 3.** Examination of the form of the deconvolution kernel  $K_U$  suggests

---

PETER HALL, SPIRIDON PENEV and JASON TRAN

---

that the Fourier transform  $f_U^{Ft}$  should not vanish at one or more points in the real line, otherwise there are poles in the integral defining  $K_U$  and a problem arises since the integral does not exist. In the numerical examples we present in this paper with the Laplace density model for  $U$ , the Fourier transform does not vanish and there is no issue. However, a more advanced construction suggested first in Hall and Meister (2007) which modifies the calculation of  $K_U$  via introduction of ridging, helps to avoid the issue even in cases where  $f_U^{Ft}$  has at most a countable number of zeros on the real line hence our Assumption A1(e).

We also note that in Fan and Truong (1993) and in other papers in the regression with measurement error literature, there is no assumptions of compact support for  $X$  whereas this assumption is utilised in the consistency proof for our procedure. At first sight, this seems a limitation of our method. However, we note that we make much less restrictive assumptions on the regression function by allowing it to even be discontinuous whereas other approaches require smoothness of the regression function (existence of derivatives of certain order). Also, we believe that the assumption of compact support of  $X$  is not too restrictive because this compact support can be made very big to satisfy all practically interesting situations. Not least, our numerical examples and experimentations demonstrate that the method performs very well even when

the support of  $X$  is not necessarily compact.

□

Additionally, we impose the following conditions on  $\hat{f}_X$  and  $\hat{f}_W$ :

*Assumption A2*

- (a) the density estimators  $\hat{f}_X$  and  $\hat{f}_W$  converge at rate  $n^{-r}$  in  $L_2$ , in the sense that  $\int_a^b (\hat{f}_X - f_X)^2 = O_p(n^{-2r})$  and  $\int_{-\infty}^{\infty} (\hat{f}_W - f_W)^2 = O_p(n^{-2r})$ , and moreover  $\sup_{w \in \mathbb{R}} |\hat{f}_W(w) - f_W(w)| = O_p(n^{-r})$  where  $0 < r < \frac{1}{2}$ ; and (b)  $m = m(n)$  diverges, subject to  $m \leq m_0(n)$  where  $m_0(n) \rightarrow \infty$  and  $2^{m_0(n)} = o(n^r)$ . □

This assumption is somewhat generous towards the estimator  $\hat{f}_W$ ; we would expect  $\hat{f}_W$  to converge to  $f_W$  an order of magnitude faster than does  $\hat{f}_X$  to  $f_X$ , although we only require the same rate for both estimators. In addition, we mention that the required polynomial convergence rate for  $\hat{f}_X$  in Assumption 2 is only possible to achieve if the distribution of  $U$  is ordinary smooth (otherwise the attainable rate is much slower (Fan and Truong , 1993)).

Define  $S(\alpha)$  as at (2.7), with  $v_i \equiv 1$  there.

**Theorem.** Assume that *Assumptions A1-A2* hold, and that the estimator  $\hat{g}$ , at (2.3), is computed using wavelet coefficients  $\hat{\alpha}_j$  and  $\hat{\alpha}_{jk}$  that minimise

PETER HALL, SPIRIDON PENEV and JASON TRAN

$S(\alpha)$ , at (2.7), with  $\hat{\alpha}$  constrained to lie in  $\mathcal{A}_m$ . Then, for all  $q \in (0, \infty)$ ,

$$\int_{[a,b]} |\hat{g} - g|^q \rightarrow 0 \quad (4.3)$$

in probability as  $n \rightarrow \infty$ .

A similar argument can be used to justify using the cross-validatory criterion  $T(q)$ , at (2.10), weighted by the square of  $\hat{f}_{W,-i}(W_i)$ :

$$T(q) = \sum_{i \in \mathcal{I}} \left\{ Y_i \hat{f}_{W,-i}(W_i) - \int \hat{g}_{-i}(x) f_U(W_i - x) \hat{f}_{X,-i}(x) dx \right\}^2.$$

At present we are able only to establish consistency, not convergence rates. With the weak modelling assumptions and the specificity of our estimation method, establishing convergence rates seems to be a challenging problem.

**Supplementary Materials.** A detailed proof of the theorem is given in a supplementary material accompanying this paper.
