A low-rank based estimation-testing procedure for matrix-covariate regression

Hung Hung and Zhi-Yu Jou

Institute of Epidemiology and Preventive Medicine

National Taiwan University, Taiwan

Abstract

Matrix-covariate is now frequently encountered in many biomedical researches. It is common to fit conventional statistical models by vectorizing matrix-covariate. This strategy, however, results in a large number of parameters, while the available sample size is relatively too small to have reliable analysis results. To overcome the problem of high-dimensionality in hypothesis testing, variance-component test has been proposed with superior detection power, but it is not straightforward to provide estimates of effect size. In this work, we overcome the problem of high-dimensionality by utilizing the inherent structure of the matrix-covariate. One advantage of the newly developed method is that estimation and hypothesis testing can be conducted simultaneously as in the conventional case, while the estimation efficiency and detection power can be largely improved. Another merit is

that, unlike existing methods, the proposed method avoids the problem of choosing identifiability constraints for the model parameters. Our method is applied to test the significance of gene-gene interactions in the PSQI data, and to test the association between electroencephalography and the alcoholic status in the EEG data.

Key words: High-dimensionality; Hypothesis testing; Low-rank; Matrix-covariate; Tensor.

1 Introduction

Techniques of detecting the association between the candidate covariate and the response variable are widely applied in many applications. Recently, matrix-covariate becomes more frequently encountered in biomedical researches, wherein the research interest focuses on the association between the response variable $Y \in \mathbb{R}$ and the $p \times q$ matrix-covariate $\boldsymbol{M} \in \mathbb{R}^{p\times q}$, possibly after adjusting for the effects of certain confounding factors $Z \in \mathbb{R}^m$. Using the Electroencephalography (EEG) data as our motivating example, Y is the binary alcoholic status, and $\boldsymbol{M}$ is a 256×64 matrix with its (j,k)-th element $\boldsymbol{M}(j,k)$ being the voltage value of the k-th electrode measured at the j-th time point. Figure 1 displays the voltage values $\boldsymbol{M}$ of one randomly selected subject from both the alcoholic group ($Y = 1$) and the control group ($Y = 0$). It can be seen that $\boldsymbol{M}|Y = 1$ tends to be larger than $\boldsymbol{M}|Y = 0$ for some (j,k) values, indicating a strong association between Y and $\boldsymbol{M}$, and it is of interest to investigate this association in a quantitative manner. Sometimes $\boldsymbol{M}$ is not directly observed but is induced from the original covariates. The Pittsburgh Sleep Quality Index (PSQI) data collects for each subject the PSQI score (Y) and the multiple measurements of the genes ROR (with 19 markers) and NR1D1 (with 4 markers). Past study have found that ROR and NR1D1 cannot explain the variation of PSQI score well, and it is suggested to fit the PSQI score on the gene-gene interactions (G×G) between ROR and NR1D1. Let $G = (g_1, \dots g_p)^\top$ denote the p-genetic markers (e.g., ROR) and let $E = (e_1, \dots e_q)^\top$ denote another q-genetic markers (e.g., NR1D1). It is equivalent to investigate if Y is associated with the pq products $\{g_j e_k : 1 \le j \le p, 1 \le k \le q\}$, or

equivalently, with the matrix-covariate $\boldsymbol{M} = GE^\top$ by noting that $\boldsymbol{M}(j,k) = g_j e_k$, after adjusting for the effects of $Z = (G^\top, E^\top)^\top$. See also Section 5 for more details of the EEG and PSQI data sets.

The research interests of the above-mentioned motivating examples all focus on the association between Y and the matrix-covariate $\boldsymbol{M}$, and two questions are commonly raised by practitioners:

(Q1) Does Y associate with $\boldsymbol{M}$?

(Q2) How does $\boldsymbol{M}$ affect Y?

To answer (Q1), a commonly used method is to fit a GLM for Y on each element of $\boldsymbol{M}$ separately, and then use the minimum p-value of the pq marginal tests as the test statistic (denoted by min-test). The min-test, however, can produce biased results due to the ignorance of the joint effects of $\boldsymbol{M}$. Joint inference is thus preferable, which fits the GLM (McCullagh and Nelder, 1989)

$$Y|(Z, \boldsymbol{M}) \sim \text{Normal}(E(Y|Z, \boldsymbol{M}), \sigma^2) \tag{1}$$

for continuous Y with a common variance σ^2, or

$$Y|(Z, \boldsymbol{M}) \sim \text{Bernoulli}(E(Y|Z, \boldsymbol{M})) \tag{2}$$

for binary Y, and assumes that

$$g\{E(Y|Z, \boldsymbol{M})\} = \gamma + \xi^\top Z + \sum_{j,k} \eta_{jk} \boldsymbol{M}(j,k), \tag{3}$$

where g is the link function, γ is the intercept term, ξ is the effect of Z, and η_{jk} is the effect of $\boldsymbol{M}(j,k)$. Following the convention, we adopt the identity link $g(u) = u$ for model (1), and adopt the logit link $g(u) = \ln \frac{u}{1-u}$ for model (2). Based on (3), answering (Q1)-(Q2) relies on estimating η_{jk}'s and testing the overall hypothesis

$$H_0 : \eta_{jk} = 0 \ \ \forall \ \ (j,k). \tag{4}$$

Although the joint method overcomes the problem of bias, it suffers the problem of high-dimensionality, since the number of parameters for η_{jk}'s, say pq, can be large in comparison with the sample size n. In the EEG data, for example, there are $256 \times 64 = 16384$ parameters for η_{jk}'s, while the available sample size is 122 only.

To overcome the problem of high-dimensionality in testing (4), Lin *et al.* (2013) apply the variance-component test (Lin, 1997) to propose GESAT. The authors extend model (3) to the generalized linear mixed model (GLMM) by assuming that η_{jk}'s independently follow an arbitrary distribution with zero mean and a common variance τ^2. As a result, testing (4) is equivalent to testing $H_0 : \tau^2 = 0$ under the GLMM, and the test statistic of GESAT is derived to be

$$T_{\text{gesat}} = \Big\| \sum_{i=1}^{n} (Y_i - \widetilde{\gamma} - \widetilde{\xi}^{\top} Z_i) \text{vec}(\boldsymbol{M}_i) \Big\|^2, \tag{5}$$

where $\{(Y_i, Z_i, \boldsymbol{M}_i)\}_{i=1}^n$ is a random sample from $(Y, Z, \boldsymbol{M})$, $\text{vec}(\boldsymbol{M}_i)$ is the pq-vector from stacking the columns of $\boldsymbol{M}_i$, and $(\widetilde{\gamma}, \widetilde{\xi})$ are the restricted MLE of (γ, ξ) under (4). GESAT has the advantage of fast computation and is shown to be locally most powerful (Goeman *et al*, 2006). GESAT, however, aims to test if Y is associated with $\boldsymbol{M}$ or not

(i.e., answering (Q1)), but is not straightforward to provide estimates of the effect sizes of $\boldsymbol{M}$ (i.e., answering (Q2)). A naive solution is to fit model (3) to obtain the estimates of η_{jk}'s, but it will again suffer the problem of high-dimensionality, and there is no guarantee that the estimates coincide with the conclusion from GESAT, either.

Another branch of methods overcome the problem of high-dimensionality by utilizing the matrix structure of $\boldsymbol{M}$. The main idea is to re-express (3) as

$$g\{E(Y|Z,\boldsymbol{M})\} = \gamma + \xi^\top Z + \mathrm{vec}(\boldsymbol{\eta})^\top \mathrm{vec}(\boldsymbol{M}), \tag{6}$$

where $\boldsymbol{\eta}$ is the $p \times q$ matrix with the (j,k)-th element being η_{jk}. Under model (6), answering (Q1)-(Q2) relies on estimating the matrix $\boldsymbol{\eta}$ and testing

$$H_0 : \boldsymbol{\eta} = \mathbf{0}_{p\times q}. \tag{7}$$

Of course there is no difference between models (3) and (6), but model (6) that preserves the matrix structure of $\boldsymbol{M}$ provides a way to more efficiently estimate $\boldsymbol{\eta}$, via utilizing the matrix structure of $\boldsymbol{\eta}$. Hung and Wang (2013) propose the *matrix-variate logistic (MV-logistic) regression* for binary Y, by fitting (6) with the rank-1 constraint $\boldsymbol{\eta} = \boldsymbol{A}\boldsymbol{B}^\top$ for some $\boldsymbol{A} \in \mathbb{R}^p$ and $\boldsymbol{B} \in \mathbb{R}^q$. Zhou, Li, and Zhu (2013) propose the *tensor regression* by fitting (6) with the rank-r constraint $\boldsymbol{\eta} = \boldsymbol{A}\boldsymbol{B}^\top$ for some $\boldsymbol{A} \in \mathbb{R}^{p\times r}$, $\boldsymbol{B} \in \mathbb{R}^{q\times r}$, and $r \geq 1$. The main advantage of these methods is that one only requires $(p+q)r$ parameters to model $\boldsymbol{\eta}$ instead of pq, and an efficiency gain in estimating $\boldsymbol{\eta}$ is reasonably expected. Tensor regression, however, has the drawback that $(\boldsymbol{A}, \boldsymbol{B})$ are not identifiable. This can be seen from $\boldsymbol{A}\boldsymbol{B}^\top = \boldsymbol{A}\boldsymbol{C}\boldsymbol{C}^{-1}\boldsymbol{B}^\top$ for any nonsingular $\boldsymbol{C} \in \mathbb{R}^{r\times r}$. To avoid this problem, both

Hung and Wang (2013) and Zhou, Li, and Zhu (2013) impose extra constraints on $(\boldsymbol{A}, \boldsymbol{B})$ so that conventional MLE arguments can be applied to develop asymptotic properties. Since the identifiability constraints are not unique, different choices of the constraints will produce different analysis results, and this fact will limit the applicabilities of these methods. Without using a parsimonious parameterization of $\boldsymbol{\eta}$, Zhou and Li (2014) propose *regularized matrix regression* by estimating $\boldsymbol{\eta}$ with the penalized MLE, where the imposed penalty function depends on $\boldsymbol{\eta}$ only through its singular values. Although regularized matrix regression avoids the problem of choosing identifiability constraint, it requires pq parameters to model $\boldsymbol{\eta}$ that can make the model fitting less efficient, especially for the case of large (p, q). Moreover, the asymptotic property of the resulting estimator is difficult to derive. We also note that the above-mentioned methods all focus on the estimation of $\boldsymbol{\eta}$ (i.e., answering (Q2)), and extensions of these methods to testing (7) (i.e., answering (Q1)) are not discussed.

The aim of this study is to propose a unified inference procedure for (Q1)-(Q2) that adapts to the high-dimensional setting, while overcomes the above-mentioned drawbacks of existing methods. Our proposal follows tensor regression by considering the joint model (6) with the rank-r constraint $\boldsymbol{\eta} = \boldsymbol{A}\boldsymbol{B}^\top$. One contribution of this work is the development of the asymptotic property that is invariant to the choice of the identifiability constraint on $(\boldsymbol{A}, \boldsymbol{B})$, which is an essential difference to the works of Hung and Wang (2013) and Zhou, Li, and Zhu (2013). Based on the developed asymptotic property, we further propose a low-rank based test statistic for (7). The proposed test statistic is

also invariant to the choice of the identifiability constraint and, hence, is more applicable in real applications. Comparing with GESAT, our method can not only improve the detection power by utilizing the matrix structure of $\boldsymbol{\eta}$, but can also provide estimate of $\boldsymbol{\eta}$ at the same time.

Some notation are defined here for the ease of reference. For any $p \times q$ matrix $\boldsymbol{M}$, $\text{vec}(\boldsymbol{M})$ is the pq-vector from stacking the columns of $\boldsymbol{M}$, $\boldsymbol{K}_{p,q}$ is the commutation matrix (Henderson and Searle, 1979) satisfying $\boldsymbol{K}_{p,q}\text{vec}(\boldsymbol{M}) = \text{vec}(\boldsymbol{M}^\top)$, and $\|\boldsymbol{M}\|_F$ denotes the Frobenius norm of $\boldsymbol{M}$. $\otimes$ stands for the Kronecker product, and $\|\cdot\|$ stands for the Euclidean norm of a vector. α denotes the significance level.

The rest of this paper is organized below. Our inference procedure for $\boldsymbol{\eta}$ is developed in Section 2, based on which the test statistics for (7) are proposed in Section 3. Section 4 conducts numerical studies to evaluate the performances of our proposal, and Section 5 conducts analyses for the PSQI and EEG data sets. The paper ends with a discussion in Section 6.

Remark 1. *The idea of treating $G\times G$ as a matrix $\boldsymbol{M} = GE^\top$ is motivated from Hung* et al. *(2016). The authors also develop asymptotic property that is invariant to the choice of the identifiability constrain, but their result can only be applied under the normal model (1). Our asymptotic property extends the result of Hung* et al. *(2016) to the more general GLM that includes models (1)-(2) as special cases. Moreover, we aim to develop test statistic for (7), and this problem is not investigated in Hung* et al. *(2016).*

2 The Low-Rank Inference Procedure for $\boldsymbol{\eta}$

2.1 Model specification

The rationale behind our proposal is based on the assumption that *most of the row and/or column attributes of* $\boldsymbol{M}$ *play no role in explaining* Y. In the EEG data, it is common that only a small portion of probes (the column attribute of $\boldsymbol{M}$) are effective to the alcoholic status. In the PSQI data, it is believed that only a few elements of ROR and NR1D1 (the row and column attributes of $\boldsymbol{M}$) are influential to the PSQI score. It implies that most of the rows and/or columns of $\boldsymbol{\eta}$ are zeros, i.e., $\boldsymbol{\eta}$ is a low-rank matrix. It is thus reasonable to consider the rank-r GLM (Hung and Wang, 2013; Zhou, Li, and Zhu, 2013):

$$g\{E(Y|Z,\boldsymbol{M})\} = \gamma + \xi^\top Z + \mathrm{vec}(\boldsymbol{\eta})^\top \mathrm{vec}(\boldsymbol{M}) \quad \text{with} \quad \boldsymbol{\eta} = \boldsymbol{A}\boldsymbol{B}^\top, \tag{8}$$

where $\boldsymbol{A} \in \mathbb{R}^{p\times r}$, $\boldsymbol{B} \in \mathbb{R}^{q\times r}$, and $1 \le r \le \min\{p,q\}$ such that $\mathrm{rank}(\boldsymbol{\eta}) = r$. Recall that $(\boldsymbol{A},\boldsymbol{B})$ are not identifiable as mentioned in Section 1. Unlike Hung and Wang (2013) and Zhou, Li, and Zhu (2013) who impose extra constraints on $(\boldsymbol{A},\boldsymbol{B})$, in this work we leave $(\boldsymbol{A},\boldsymbol{B})$ arbitrary to develop our inference procedure for $\boldsymbol{\eta}$. This is achievable since we are interested in $\boldsymbol{\eta}$ instead of $(\boldsymbol{A},\boldsymbol{B})$, and only the identifiability of $\boldsymbol{A}\boldsymbol{B}^\top$ is required. We will see in Section 2.3 that the developed asymptotic property depends on $(\boldsymbol{A},\boldsymbol{B})$ only through $\mathrm{span}(\boldsymbol{A})$ and $\mathrm{span}(\boldsymbol{B})$. As a result, we are allowed to use the convenient parameterization $\boldsymbol{\eta} = \boldsymbol{A}\boldsymbol{B}^\top$ to make inference about $\boldsymbol{\eta}$ without imposing any constraint on $(\boldsymbol{A},\boldsymbol{B})$, which makes our method more applicable in practice.

One advantage of model (8) is the parsimony of parameters. The conventional model

(3) requires $1 + m + pq$ parameters. Since one only requires $(p + q - r)r$ parameters to specify a rank-r $p \times q$ matrix, the effective number of parameters in model (8) is

$$s_r = 1 + m + (p + q - r)r. \tag{9}$$

Comparing s_r with $1+m+pq$, we expect an efficiency gain by fitting model (8) when r is small. We note that the effective number of parameters s_r is only used to have an insight about the advantage of model (8). The development of the inference procedures for $\boldsymbol{\eta}$ in the subsequent sections are still based on the convenient parameterization $\boldsymbol{\eta} = \boldsymbol{A}\boldsymbol{B}^\top$ without imposing any constraint on $(\boldsymbol{A}, \boldsymbol{B})$.

2.2 Estimation and implementation

Let the data $\{(Y_i, Z_i, \boldsymbol{M}_i)\}_{i=1}^n$ be random copies of $(Y, Z, \boldsymbol{M})$, and let the vector of covariates be $X_i = (1, Z_i^\top, \mathrm{vec}(\boldsymbol{M}_i)^\top)^\top$. Let

$$\theta = (\gamma, \xi^\top, \mathrm{vec}(\boldsymbol{A})^\top, \mathrm{vec}(\boldsymbol{B})^\top)^\top \tag{10}$$

be the parameters of model (8), and let the induced parameters of interest be

$$\beta = \beta(\theta) = (\gamma, \xi^\top, \mathrm{vec}(\boldsymbol{A}\boldsymbol{B}^\top)^\top)^\top, \tag{11}$$

which consists of the intercept, the effect of Z, and the effect of $\boldsymbol{M}$.

The log-likelihood function of θ is $\frac{n}{\sigma^2}\ell(\theta) - \frac{n}{2}\ln(2\pi\sigma^2)$ with

$$\ell(\theta) = -\frac{1}{2n}\sum_{i=1}^{n}\{Y_i - \beta(\theta)^\top X_i\}^2 \tag{12}$$

under normal model (1), and is

$$\ell(\theta) = \frac{1}{n}\sum_{i=1}^{n} Y_i\{\beta(\theta)^\top X_i\} - \ln[1+\exp\{\beta(\theta)^\top X_i\}] \tag{13}$$

under logistic model (2). To stabilize the estimation process, a widely used strategy is the penalized MLE. A natural choice of the penalty is $\|\boldsymbol{A}\boldsymbol{B}^\top\|_F^2$. The penalty $\|\boldsymbol{A}\boldsymbol{B}^\top\|_F^2$, however, may cause certain instability of implementation. Since $\|\boldsymbol{A}\boldsymbol{B}^\top\|_F \le \|\boldsymbol{A}\|_F\|\boldsymbol{B}\|_F$, we propose to estimate θ by

$$\widehat{\theta} = \underset{\theta}{\operatorname{argmax}} \Big\{\ell(\theta) - \frac{1}{2}\lambda\|\boldsymbol{A}\|_F^2\|\boldsymbol{B}\|_F^2\Big\}, \tag{14}$$

where $\lambda \ge 0$ controls the effect of penalty. That is, we use an upper bound of $\|\boldsymbol{A}\boldsymbol{B}^\top\|_F^2$ as the penalty term. As will be shown in (16)-(17) later, the merit of using $\|\boldsymbol{A}\|_F^2\|\boldsymbol{B}\|_F^2$ is that (14) can be obtained by iteratively solving the conventional L_2-penalized MLE problem, where existing algorithm can be directly applied (Le Cessie and Van Houwelingen, 1992). With $\widehat{\theta}$ being obtained, β is estimated by

$$\widehat{\beta} = \beta(\widehat{\theta}) = (\widehat{\gamma}, \widehat{\xi}^\top, \mathrm{vec}(\widehat{\boldsymbol{\eta}})^\top)^\top \quad \text{with} \quad \widehat{\boldsymbol{\eta}} = \widehat{\boldsymbol{A}}\widehat{\boldsymbol{B}}^\top. \tag{15}$$

Obviously, the performance of $\widehat{\beta}$ depends on the values of (r, λ). A simple idea is to select both (r, λ) by cross-validation. Note that $\widehat{\beta}$ is a continuous function of λ, but the continuity does not hold for the discrete parameter r. It indicates that $\widehat{\beta}$ is more sensitive to the selection of r. Alternatively, we propose a more stable selection criterion for r via the number of effective parameters s_r. First observe that an over-specification of r will not affect the consistency of $\widehat{\beta}$, while an under-specification of r will make $\widehat{\beta}$ biased. It

suggests that a large r should be used to ensure the validity of $\widehat{\beta}$. On the other hand, we also prefer a small r such that the rank-r GLM can be well fitted with sample size n. Consequently, we are motivated to select r as large as possible while keeping s_r relatively smaller than n (e.g., $n/s_r \geq 3$). That is, we suggest to select a large r such that the rank-r GLM is more plausible to be a correct model, while preserving the estimation efficiency of $\widehat{\beta}$ with limited sample size. With a fixed r, λ is selected by cross-validation.

To implement our method, we use the alternating method to solve (14). First note that model (8) can be expressed as

$$g\{E(Y|Z)\} = \gamma + \xi^\top Z + \mathrm{vec}(\boldsymbol{A})^\top \mathrm{vec}(\boldsymbol{MB}) \quad (16)$$

$$= \gamma + \xi^\top Z + \mathrm{vec}(\boldsymbol{B})^\top \mathrm{vec}(\boldsymbol{M}^\top \boldsymbol{A}). \quad (17)$$

Observe that (16) is the GLM with parameters $(\gamma, \xi^\top, \mathrm{vec}(\boldsymbol{A})^\top)^\top$ and data $(Y, Z, \boldsymbol{MB})$. Thus, when $\boldsymbol{B}$ is fixed, maximizing (14) becomes the conventional L_2-penalized MLE problem under model (16) with penalty $\frac{1}{2}\lambda_{\boldsymbol{B}}$ for $\|\boldsymbol{A}\|_F^2$, where $\lambda_{\boldsymbol{B}} = \lambda\|\boldsymbol{B}\|_F^2$. The case for fixed $\boldsymbol{A}$ is similar by using the data $(Y, Z, \boldsymbol{M}^\top \boldsymbol{A})$ to fit model (17) with parameters $(\gamma, \xi^\top, \mathrm{vec}(\boldsymbol{B})^\top)^\top$ and penalty $\frac{1}{2}\lambda_{\boldsymbol{A}}$ for $\|\boldsymbol{B}\|_F^2$, where $\lambda_{\boldsymbol{A}} = \lambda\|\boldsymbol{A}\|_F^2$. We then iterate the roles of $\boldsymbol{A}$ and $\boldsymbol{B}$ until convergence. The implementation algorithm is summarized below.

Alternating Algorithm

---

1. Given an initial value $\boldsymbol{B}_{(0)}$. For $k = 0, 1, 2, \ldots,$ do the following Steps 2-4.

2. Given $\boldsymbol{B}_{(k)}$, obtain the L_2-penalized MLE $(\gamma^*_{(k+1)}, \xi^*_{(k+1)}, \boldsymbol{A}_{(k+1)})$ from fitting (16) on the data $\{(Y_i, Z_i, \boldsymbol{M}_i\boldsymbol{B}_{(k)})\}_{i=1}^n$ with the penalty $\frac{1}{2}\lambda_{\boldsymbol{B}_{(k)}}$ for $\|\boldsymbol{A}\|_F^2$.

3. Given $\boldsymbol{A}_{(k+1)}$, obtain the L_2-penalized MLE $(\gamma_{(k+1)}, \xi_{(k+1)}, \boldsymbol{B}_{(k+1)})$ from fitting (17) on the data $\{(Y_i, Z_i, \boldsymbol{M}_i^\top \boldsymbol{A}_{(k+1)})\}_{i=1}^n$ with the penalty $\frac{1}{2}\lambda_{\boldsymbol{A}_{(k+1)}}$ for $\|\boldsymbol{B}\|_F^2$.

4. Let $\theta_{(k+1)} = (\gamma_{(k+1)}, \xi_{(k+1)}^\top, \mathrm{vec}(\boldsymbol{A}_{(k+1)})^\top, \mathrm{vec}(\boldsymbol{B}_{(k+1)})^\top)^\top$. Repeat the procedure until the convergence of $\beta(\theta_{(k+1)})$. Output $\widehat{\beta} = \beta(\theta_{(\infty)})$ and $\widehat{\theta} = \theta_{(\infty)}$.

For each iteration, the maximum log-likelihood attained in either Step 2 or Step 3 of Alternating Algorithm cannot decrease. To see this, let $f(\gamma, \xi, \boldsymbol{A}, \boldsymbol{B}) = \ell(\theta) - \frac{\lambda}{2}\|\boldsymbol{A}\|_F^2\|\boldsymbol{B}\|_F^2$ be the objective function being maximized. We must have

$$f(\gamma_{(k)}, \xi_{(k)}, \boldsymbol{A}_{(k)}, \boldsymbol{B}_{(k)}) \overset{\text{Step 2}}{\leq} f(\gamma^*_{(k+1)}, \xi^*_{(k+1)}, \boldsymbol{A}_{(k+1)}, \boldsymbol{B}_{(k)}) \overset{\text{Step 3}}{\leq} f(\gamma_{(k+1)}, \xi_{(k+1)}, \boldsymbol{A}_{(k+1)}, \boldsymbol{B}_{(k+1)}).$$

Since f is bounded by 0, the algorithm must converge to a local maximum. Note also that the algorithm depends on the selection of an initial value $\boldsymbol{B}_{(0)}$. We suggest to choose $\boldsymbol{B}_{(0)}$ as the leading r right singular vectors of $\widetilde{\boldsymbol{\eta}}$, where $\widetilde{\boldsymbol{\eta}}$ is the L_2-penalized MLE of $\boldsymbol{\eta}$ under the conventional model (6). It is also suggested to use multiple random initial values to find the global maximum.

2.3 Asymptotic property

We now proceed to derive the asymptotic property of $\widehat{\beta}$. Let $\beta_0 = (\gamma_0, \xi_0^\top, \mathrm{vec}(\boldsymbol{\eta}_0)^\top)^\top$ be the true value of β under model (8), and assume the existence of a regular point (Shapiro, 1986) θ_0 in the parameter space of θ such that $\beta_0 = \beta(\theta_0)$. Define

$$\boldsymbol{\Delta}(\theta) = \frac{\partial \beta(\theta)}{\partial \theta} = \begin{bmatrix} \boldsymbol{I}_{m+1} & \boldsymbol{0} & \boldsymbol{0} \\ \boldsymbol{0} & (\boldsymbol{B} \otimes \boldsymbol{I}_p) & (\boldsymbol{I}_q \otimes \boldsymbol{A})\boldsymbol{K}_{q,r} \end{bmatrix} \tag{18}$$

and let $\boldsymbol{\Delta}_0 = \boldsymbol{\Delta}(\theta_0)$. The asymptotic property of $\widehat{\beta}$ is stated below, and its proof is deferred to Supplementary Materials.

Theorem 1. *Assume the validity of model (8) with* $\beta_0 = \beta(\theta_0)$ *and* $\mathrm{rank}(\boldsymbol{\Delta}_0) = s_r$. *Assume also that* $\lambda = o_p(n^{-1/2})$. *Then, with fixed* (p, q) *and as* $n \to \infty$, $\sqrt{n}(\widehat{\beta} - \beta_0) \xrightarrow{d} N(\mathbf{0}, \boldsymbol{\Sigma}_0)$ *with the asymptotic covariance matrix* $\boldsymbol{\Sigma}_0 = \boldsymbol{\Delta}_0(\boldsymbol{\Delta}_0^\top \boldsymbol{V}_0 \boldsymbol{\Delta}_0)^+ \boldsymbol{\Delta}_0^\top$, *where*

(a) $\boldsymbol{V}_0 = \sigma^{-2} E[X_i X_i^\top]$ *for the normal model (1);*

(b) $\boldsymbol{V}_0 = E[\nu_i(\theta_0) X_i X_i^\top]$ *with* $\nu_i(\theta) = \frac{\exp\{\beta(\theta)^\top X_i\}}{[1+\exp\{\beta(\theta)^\top X_i\}]^2}$ *for the logistic model (2).*

The asymptotic property of $\widehat{\beta}$ will be the core to develop our test statistics in Section 3. We propose to estimate the asymptotic covariance matrix $\boldsymbol{\Sigma}_0$ by the sandwich-type estimator

$$\widehat{\boldsymbol{\Sigma}} = \widehat{\boldsymbol{\Delta}} \left\{ \widehat{\boldsymbol{\Delta}}^\top (\widehat{\boldsymbol{V}} + \lambda \boldsymbol{D}) \widehat{\boldsymbol{\Delta}} \right\}^+ \widehat{\boldsymbol{\Delta}}^\top \widehat{\boldsymbol{V}} \widehat{\boldsymbol{\Delta}} \left\{ \widehat{\boldsymbol{\Delta}}^\top (\widehat{\boldsymbol{V}} + \lambda \boldsymbol{D}) \widehat{\boldsymbol{\Delta}} \right\}^+ \widehat{\boldsymbol{\Delta}}^\top, \tag{19}$$

where $\widehat{\boldsymbol{\Delta}} = \boldsymbol{\Delta}(\widehat{\theta})$, $\widehat{\boldsymbol{V}} = \widehat{\sigma}^{-2} \cdot \frac{1}{n} \sum_{i=1}^n X_i X_i^\top$ with $\widehat{\sigma}^2 = \frac{1}{n - s_r} \sum_{i=1}^n (Y_i - \widehat{\beta}^\top X_i)^2$ for the case of (1) and $\widehat{\boldsymbol{V}} = \frac{1}{n} \sum_{i=1}^n \nu_i(\widehat{\theta}) X_i X_i^\top$ for the case of (2), and $\boldsymbol{D}$ is a block-diagonal matrix with diagonal elements $(\mathbf{0}_{1+m}, \|\widehat{\boldsymbol{B}}\|_F^2 \boldsymbol{I}_{pr}, \|\widehat{\boldsymbol{A}}\|_F^2 \boldsymbol{I}_{qr})$.

3 Detecting the Significance of $\boldsymbol{\eta}$

3.1 The low-rank based test statistic

This section aims to develop test statistics for the null hypothesis (7). We start by illustrating some strategies based on either the rank-r GLM (8) or existing method, and

discuss the possible drawbacks of them. We then propose a combined test statistic that is able to adapt to various situations.

A natural strategy to test (7) via model (8) is to use the Wald-test statistic

$$T_{\text{wald}} = \text{vec}(\widehat{\boldsymbol{\eta}})^\top \left\{ [\widehat{\boldsymbol{\Sigma}}]_{\boldsymbol{\eta}}/n \right\}^+ \text{vec}(\widehat{\boldsymbol{\eta}}), \tag{20}$$

where $[\widehat{\boldsymbol{\Sigma}}]_{\boldsymbol{\eta}}$ is the sub-matrix of $\widehat{\boldsymbol{\Sigma}}$ that corresponds to the asymptotic covariance matrix of $\text{vec}(\widehat{\boldsymbol{\eta}})$ in Theorem 1. Note that $[\widehat{\boldsymbol{\Sigma}}]_{\boldsymbol{\eta}}$ is singular due to the over-parameterization of $\boldsymbol{\eta} = \boldsymbol{A}\boldsymbol{B}^\top$, and the Moore-Penrose generalized inverse is used. Observe that T_{wald} is a weighted sum over the differences $(\widehat{\boldsymbol{\eta}} - \mathbf{0})$. Thus, T_{wald} can be less powerful in testing (7) when $\boldsymbol{\eta}$ is sparse, as the contribution of differences can be averaged out during summation. In view of this point, a better strategy to test (7) with sparse $\boldsymbol{\eta}$ is to use the test statistic

$$T_{\max} = \max_{l \in \{m+2, \ldots, 1+m+pq\}} \frac{\widehat{\beta}_l^2}{[\widehat{\boldsymbol{\Sigma}}]_{\beta_l}/n}, \tag{21}$$

where the maximum is taken over the estimates of $\boldsymbol{\eta}$. $T_{\max}$ is a generalization of min-test, in the sense that $T_{\max}$ further considers the joint effects among $\boldsymbol{M}$. Different from $(T_{\text{wald}}, T_{\max})$ that utilize the low-rank structure of $\boldsymbol{\eta}$, T_{gesat} uses the technique of variance-component test to overcome the problem of high-dimensionality. As mentioned in Section 1, T_{gesat} is shown to be locally most powerful. T_{gesat} is thus expected to have superior performance when $\boldsymbol{\eta}$ has weak effect. However, there is no guarantee for its performance otherwise. Moreover, ignoring the low-rank structure of $\boldsymbol{\eta}$, which is plausible to be true in many applications, may also decrease the detection power of T_{gesat}.

Obviously, $(T_{\text{wald}}, T_{\max}, T_{\text{gesat}})$ have their own merits in testing (7), depending on the underlying characteristic of $\boldsymbol{\eta}$. T_{wald} is preferred when $\boldsymbol{\eta}$ has dense effect, $T_{\max}$ is preferred

when $\boldsymbol{\eta}$ has sparse effect, and T_{gesat} is preferred when $\boldsymbol{\eta}$ has weak effect. Ideally, one should choose the test statistic according to the alternative hypothesis, which is rarely known a priori. A reasonable strategy is to combine $(T_{\text{wald}}, T_{\max}, T_{\text{gesat}})$ to adapt to various situations. There exist many combination methods based on the p-values, but they are not applicable in our case since the limiting distribution of $T_{\max}$ is not easy to derive. Alternatively, we propose to use the product

$$T \;=\; T_{\text{wald}} \cdot T_{\max} \cdot T_{\text{gesat}} \tag{22}$$

as the test statistic, and a large value of T indicates a rejection of (7). The advantage of the multiplicative combination is that T is less affected by the scales of $(T_{\text{wald}}, T_{\max}, T_{\text{gesat}})$. We emphasize that T is developed based on the asymptotic property in Theorem 1 and, hence, is also invariant to the choice of the identifiability constraint of $(\boldsymbol{A}, \boldsymbol{B})$.

Remark 2. *Besides the overall hypothesis (7), one can also identify the significant covariates $\boldsymbol{M}(j,k)$'s by considering the pq individual hypotheses*

$$H_0^{(jk)} : \eta_{jk} = 0, \quad 1 \le j \le p, \quad 1 \le k \le q. \tag{23}$$

Let ρ_{jk} be the p-value of $\frac{\widehat{\beta}_l^2}{[\widehat{\boldsymbol{\Sigma}}]_{\beta_l}/n}$, where l is such that $\beta_l = \eta_{jk}$. The identified significant covariates are $\{\boldsymbol{M}(j,k) : \rho_{jk} < \frac{\alpha}{pq}, 1 \le j \le p, 1 \le k \le q\}$ with the family-wise error rate being controlled at α by Bonferroni correction.

3.2 Calculation of p-value

Since the null distribution of T is not straightforward to derive, we propose to use parametric bootstrap to obtain its p-value. The idea of parametric bootstrap as summarized below is to generate the null data from model (8) given $(\gamma, \xi, \boldsymbol{\eta}) = (\widetilde{\gamma}, \widetilde{\xi}, 0)$, where $(\widetilde{\gamma}, \widetilde{\xi})$ are the restricted MLE of (γ, ξ) under H_0 (Bůžková, Lumely, and Rice, 2011).

Parametric bootstrap test

---

1. Conditional on $(Z_i, \boldsymbol{M}_i)$, generate $Y_i^{(b)}$ from model (8) with $(\gamma, \xi, \boldsymbol{\eta}) = (\widetilde{\gamma}, \widetilde{\xi}, 0)$ (and with $\sigma^2 = \frac{1}{n-(m+1)} \sum_{i=1}^{n} (Y_i - \widetilde{\gamma} - \widetilde{\xi}^\top Z_i)^2$ for normal model). Obtain the test statistic $T^{(b)}$ by fitting model (8) using $\{(Y_i^{(b)}, Z_i, \boldsymbol{M}_i)\}_{i=1}^n$.

2. Obtain the p-value of T by $\frac{1}{b'} \sum_{b=1}^{b'} I(T^{(b)} > T)$ for a large number b'.

Although parametric bootstrap procedure can be applied in various situations, its performance depends on the randomness of $(\widetilde{\gamma}, \widetilde{\xi})$. As a result, using parametric bootstrap can only control the type-I error asymptotically. Alternatively, an exact test can be constructed when Z_i vanishes, i.e., when model (8) reduces to

$$g\{E(Y|\boldsymbol{M})\} = \gamma + \mathrm{vec}(\boldsymbol{\eta})^\top \mathrm{vec}(\boldsymbol{M}) \quad \text{with} \quad \boldsymbol{\eta} = \boldsymbol{A}\boldsymbol{B}^\top. \tag{24}$$

In this situation, the null data can be simply generated by randomly permuting Y_i to destroy its connection with $\boldsymbol{M}_i$. The implementation algorithm is summarized below.

Permutation test

---

1. Generate $\{Y_i^{(b)}\}_{i=1}^n$ by randomly permutating $\{Y_i\}_{i=1}^n$. Obtain the test statistic $T^{(b)}$ by fitting model (24) using $\{(Y_i^{(b)}, \boldsymbol{M}_i)\}_{i=1}^n$.

2. Obtain the p-value of T by $\frac{1}{b'}\sum_{b=1}^{b'} I(T^{(b)} > T)$ for a large number b'.

We remind the readers that the permutation test cannot be applied in the presence of Z. The main reason is that permuting Y destroys not only its connection with $\boldsymbol{M}$ but also its connection with Z, which makes the resulting p-value biased. Both re-sampling procedures are suggested to obtain the p-values, according to the underlying data structure. Moreover, these procedures can also be used to obtain the p-values of $(T_{\text{wald}}, T_{\max})$, and the p-values ρ_{jk}'s of the individual tests discussed in Remark 2.

4 Simulation Studies

4.1 Simulation settings

Simulation studies are conducted to evaluate our method, where we use the PSQI and EEG data sets (see Section 5 for detailed descriptions) to generate the simulation data:

(PSQI) Let $Z = (G^\top, E^\top)^\top$ and $\boldsymbol{M} = GE^\top$, where $G \in \mathbb{R}^{15}$ and $E \in \mathbb{R}^7$ are randomly generated from ROR and NR1D1 of the PSQI data with $n = 400$. Given $(Z, \boldsymbol{M})$, Y is generated from the normal model (1) and (8) with $\gamma = 10$.

(EEG) The matrix $\boldsymbol{M} \in \mathbb{R}^{6\times 6}$ is generated by randomly selecting 6 rows and 6 columns of the EEG signals with $n = 150$. Given $\boldsymbol{M}$, Y is generated from the logistic model (2)

and (24) with $\gamma = 0$.

We consider three simulation studies, each with different specifications of $(\xi, \boldsymbol{\eta})$. The first study evaluates the asymptotic property of $\widehat{\beta}$ established in Theorem 1 (Section 4.2), the second study evaluates the performance of the proposed test method T (Section 4.3), and the third study evaluates the performance of T with larger rank$(\boldsymbol{\eta})$ or (p, q) values (Section 4.4). Simulation results from fitting the rank-r GLM with $r = 3$ are reported with 500 replicates.

4.2 Evaluation of $\widehat{\beta}$

In this simulation study we set

$$\boldsymbol{\eta} = \begin{bmatrix} \boldsymbol{\eta}_{11} & \mathbf{0}_{2\times(q-1)} \\ \mathbf{0}_{(p-2)\times 1} & \mathbf{0}_{(p-2)\times(q-1)} \end{bmatrix} \text{ with } \quad \boldsymbol{\eta}_{11} = \frac{1}{\sqrt{2}} \cdot \mathbf{1}_2,$$

and set $\xi = (\xi_G^\top, \mathbf{0}_{p-5}^\top, \xi_E^\top, \mathbf{0}_{q-3}^\top)^\top$ with $\xi_G = \frac{1}{10\sqrt{5}}\mathbf{1}_5$ and $\xi_E = \frac{1}{10\sqrt{3}}\mathbf{1}_3$ for the PSQI-simulation. Simulation results are reported in Table 1, which provides the means and standard deviations (SD) of $\widehat{\beta}$, the standard errors (SE) from the means of the diagonal elements of $\widehat{\boldsymbol{\Sigma}}$ corresponding to $(\gamma, \xi_G, \xi_E, \boldsymbol{\eta}_{11})$, and the averaged mean squared error $\text{AMSE}_\beta = E\|\widehat{\beta} - \beta\|^2/(1 + m + pq)$. We also report the averaged mean squared errors $\text{AMSE}_\xi = E\|\widehat{\xi} - \xi\|^2/m$ and $\text{AMSE}_{\boldsymbol{\eta}} = E\|\widehat{\boldsymbol{\eta}} - \boldsymbol{\eta}\|^2/(pq)$ to summarize the performance of $\widehat{\beta}$ corresponding to the vector and matrix parameters $(\xi, \boldsymbol{\eta})$.

One can see that the biases of $\widehat{\beta}$ arise under both PSQI and EEG settings, but they are relatively small in comparison with the corresponding SDs. Together with the small

values of AMSE_β, AMSE_ξ, and $\text{AMSE}_{\boldsymbol{\eta}}$, $\widehat{\beta}$ is demonstrated to be a consistent estimator. Moreover, the similar values of SDs and SEs support the validity of $\widehat{\boldsymbol{\Sigma}}$. Note that in this simulation, the true rank of $\boldsymbol{\eta}$ is 1, but the specified rank of model (8) is 3, indicating that over-specification of the rank parameter r will not affect the validity of Theorem 1. Recall also that it only requires s_r parameters in model (8), instead of $1+m+pq$ parameters in the conventional model (6). Consequently, the asymptotic results of Theorem 1 are more plausible to be true even with limited sample size as shown in Table 1. In summary, our simulation studies demonstrate the validity and applicability of the proposed $(\widehat{\beta}, \widehat{\boldsymbol{\Sigma}})$.

4.3 Evaluation of T

This section evaluates the performance of T in testing (7). To make the comparisons more informative, we consider the following two types of $\boldsymbol{\eta}$ with different effect sizes c:

(S1) $\boldsymbol{\eta}$ has zero effects except for 2 randomly selected elements, where their values are given by cU with $U \in \mathbb{R}^2$ being generated from the unit sphere.

(S2) $\boldsymbol{\eta}$ has zero effects except for a 5×2 sub-matrix, where their values are given by cU with $U \in \mathbb{R}^{10}$ being generated from the unit sphere.

The above settings give $\text{rank}(\boldsymbol{\eta}) = 2$. We set $\xi = (\xi_G^\top, \mathbf{0}_{p-5}^\top, \xi_E^\top, \mathbf{0}_{q-3}^\top)^\top$ with $\xi_G = \frac{c}{10\sqrt{5}}\mathbf{1}_5$ and $\xi_E = \frac{c}{10\sqrt{3}}\mathbf{1}_3$ for the PSQI-simulation. To implement T, we use 10-fold cross-validation to select $\lambda \in \{\frac{(p+q-r)r}{\sqrt{n}\log(n)}, \frac{(p+q-r)r}{n}, \frac{(p+q-r)r}{n^{3/2}}\}$ such that the condition $\lambda = o_p(n^{-1/2})$ is satisfied, where $(p+q-r)r$ is the number of parameters used to specify $\boldsymbol{\eta}$ with rank r. Besides T, we also implement $(T_{\text{wald}}, T_{\max}, T_{\text{gesat}})$ for comparisons. Note that $(T_{\text{wald}}, T_{\max})$ are

constructed from the rank-r GLM solely, while T_{gesat} is from the variance-component test without using the matrix structure of $\boldsymbol{\eta}$. Comparing T with $(T_{\text{wald}}, T_{\max}, T_{\text{gesat}})$ can reveal possible drawbacks of different methods. For fair comparisons, we use the same re-sampling scheme to obtain the p-values of all methods, and their power functions at the significance level 0.05 over different effect sizes c are reported in Figure 2.

At $c = 0$, one can see that all methods control the type-I errors at 0.05 approximately, which implies the validity of the re-sampling schemes (parametric bootstrap or permutation) to obtain valid p-values.

We next compare the detection powers of $(T_{\text{wald}}, T_{\max}, T_{\text{gesat}})$ at $c > 0$. For the case of small effect size c, T_{gesat} is detected to have better performance than $(T_{\text{wald}}, T_{\max})$. This is reasonable since T_{gesat} is shown to be the locally most powerful test. For the case of moderate effect size c, however, T_{wald} outperforms T_{gesat} in all settings, which indicates the gain from considering the low-rank structure of $\boldsymbol{\eta}$. Recall that $T_{\max}$ is designed to test (7) with sparse $\boldsymbol{\eta}$, and we can detect a better performance of $T_{\max}$ under (S1) than under (S2). The above observations reflect the fact that $(T_{\text{wald}}, T_{\max}, T_{\text{gesat}})$ have their own merits in testing (7), depending on the underlying characteristic of $\boldsymbol{\eta}$. By combing these methods, T is detected to be the best performer in all situations. In particular, T has detection powers comparable to the locally most powerful test T_{gesat} for small c, and has higher detection powers than $(T_{\text{wald}}, T_{\max})$ when c is moderate to large. In summary, our simulation results demonstrate the applicability of T regardless of the form of $\boldsymbol{\eta}$.

4.4 Evaluation of T with larger rank($\boldsymbol{\eta}$) or (p, q)

We consider two extensions of the simulation studies to evaluate the performance of T.

In the first extension, we use the same setting as (S2) in Section 4.3 except that the non-zero sub-matrix of $\boldsymbol{\eta}$ is of size 5×3 with $\text{rank}(\boldsymbol{\eta}) = 3$ or 5×4 with $\text{rank}(\boldsymbol{\eta}) = 4$. We note that for the case of $\text{rank}(\boldsymbol{\eta}) = 4$, the fitted rank-3 GLM is not a correct model. Simulation results from both the PSQI and EEG data sets are placed in Figure 3. It can be seen that both $T_{\max}$ and T_{gesat} have similar performances with the results of (S2) in Figure 2, while $T_{\max}$ is more sensitive to the increase of $\text{rank}(\boldsymbol{\eta})$. This is reasonable since $T_{\max}$ is specifically designed for the case of sparse $\boldsymbol{\eta}$. Despite the adverse influence of $T_{\max}$, the combined test statistic T is still found to be the best performer with the highest detection powers, even when the model rank is under-specified. This extended simulation demonstrates that T is able to adapt to various situations of $\boldsymbol{\eta}$.

In the second extension, we use the same setting with PSQI-simulation in Section 4.3 except that $G = (G_1^\top, G_2^\top)^\top$ and $E = (E_1^\top, E_2^\top)^\top$, where $G_1 \in \mathbb{R}^{15}$ and $E_1 \in \mathbb{R}^7$ are randomly generated from ROR and NR1D1 of the PSQI data, and $G_2 \in \mathbb{R}^{15}$ and $E_2 \in \mathbb{R}^8$ are randomly generated from multivariate normal distribution with zero mean and identity covariance matrix. Note that in this case, the number of parameters for $\boldsymbol{\eta}$ in the conventional model (6) is $30 \times 15 = 450$, which is larger than the sample size 400. Simulation results from fitting the rank-3 GLM are placed in Figure 4. Generally, a similar conclusion as Section 4.3 can be made for the good performance of T. For $c = 0$, the type-I errors of all methods are well controlled at 0.05. We next compare the detection powers

at $c > 0$. Unlike the simulation results in Section 4.3, T_{gesat} is found to have the lowest detection powers under both (S1)-(S2), indicating that the performance of T_{gesat} can be questionable when $pq > n$. On the other hand, T still outperforms $(T_{\text{wald}}, T_{\max}, T_{\text{gesat}})$ with the highest detection powers for all settings. It confirms that T is less affected by the problem of high-dimensionality, and is applicable even in the case of $pq > n$.

5 Data Analyses

5.1 The PSQI data

The Pittsburgh Sleep Quality Index (PSQI) data set (Lai *et al.*, 2014) includes 359 subjects with an average age of 41 years old (ranges from 18 to 69). The participants consist of 214 females and 145 males. For each subject, markers on 2 genes are collected: ROR with 19 markers (G) and NR1D1 with 4 markers (E). Also collected for each subject are the assessments of sleep quantity from Buysse *et al.* (1989), which consists of seven sores of PSQI: sleep quality, sleep latency, sleep duration, habitual sleep efficiency, sleep disturbance, use of sleeping medication, and daytime dysfunction.

In our analysis, we consider the response Y to be the log-transformation of the sum of all PSQI scores (plus one to avoid taking logarithm of 0). Let $\boldsymbol{M} = GE^{\top}$ be the 19×4 matrix of the interactions ROR×NR1D1, and let Z consist of ROR, NR1D1, Age, and Gender as possible confounding factors. Past study have found that ROR and NR1D1 cannot explain the variation of PSQI score well, and our interest focuses on

whether the PSQI score is associated with ROR×NR1D1, after adjusting for the effects of Z. Fitting the normal model (8) with $r = 3$ gives the p-value (from parametric bootstrap test) of T to be 0.008, while the p-value of T_{gesat} is 0.178. Thus, only the proposed low-rank based test method declares that ROR×NR1D1 is influential to the PSQI score. We further find that the p-value of $T_{\max}$ is smaller than 10^{-3}, while the p-value of T_{wald} is 0.145. It indicates that a sparse ROR×NR1D1 effect can be expected. The estimated effect sizes of ROR×NR1D1 is reported in Table 2, where the significant effects identified by individual tests (23) at the family-wise error rate 0.05 are marked as bold. In particular, two interactions rs11144047×rs12941497 and rs1327836×rs12941497 are identified, which confirms the spare effect of ROR×NR1D1. We note that rs11144047, rs1327836, and the interaction rs1327836×rs12941497 have been found to associate with bipolar disorder (Lai *et al.*, 2015), and bipolar disorder is known to associate with the PSQI score. Our analysis results not only support the findings in the literature, but also suggest rs11144047×rs12941497 to be an influential interaction to bipolar disorder that is missed by the conventional analysis.

5.2 The EEG data

The EEG data can be obtained from the *UCI Machine Learning Repository*, which contains 77 subjects in alcoholic group ($Y = 1$) and 45 subjects in control group ($Y = 0$). The voltage values of 64 channels at 256 time points are also collected for multiple trials, and we follow Hung and Wang (2013) to use the means over all trials to summarize the

data. It gives for each of 122 subjects 64×256 measurements. The EEG data has been analyzed by Hung and Wang (2013) and Zhou and Li (2014), where the authors report the effects of the EEG signals from their methods. The authors also report the classification accuracies from their models to support a close connection between the EEG signals and the alcoholic status. Hung and Wang (2013) and Zhou and Li (2014), however, do not test if the EEG signals are truly associated with the alcoholic status via the overall hypothesis (7), nor identify the significant covariates via the individual hypothesis (23). The aim of our analysis is to answer these questions via the proposed test method.

In our analysis, we pre-process the original covariates by averaging the voltage values for every 8 time points. It gives for each subject a 32×64 matrix-covariate $\boldsymbol{M}$ (after component-wisely standardization such that $\boldsymbol{M}(j,k)$ has mean 0 and variance 1), where $\boldsymbol{M}(j,k)$ represents the average voltage value of the k-th channel over the time period $[8(j-1)+1, 8j]$. By fitting the logistic model (8) with $r = 1$ on $(Y, \boldsymbol{M})$, we obtain the p-value of T (from permutation test) to be smaller than 10^{-3}. It indicates a strong association between the EEG signals and the alcoholic status. The significant covariates in $\boldsymbol{M}$ identified by the individual tests (23) at the family-wise error rate 0.05 are listed in Table 3. One can see that the regions Parietal and Occipital, which control the functions of sensation and vision, respectively, play important roles to the alcoholic status. Moreover, most of the identified channels have significant influence at the 11-th time period, indicating an early reaction of the brain to the stimuli. Our analysis not only provides an evidence to support the conclusions of Hung and Wang (2013) and Zhou and

Li (2014), but also suggests possible brain regions and reaction time periods for further investigations. We remind the readers that our result is obtained without imposing any identifiability constraint, which is another difference to the analyses of Hung and Wang (2013) and Zhou and Li (2014).

6 Conclusion

We propose novel methods to test the significance of matrix-covariate, and to identify the significant covariates of matrix-covariate. The rationale of our proposal is to utilize the matrix structure of $\boldsymbol{\eta}$ to achieve a parsimonious parameterization and, hence, a higher detection power than conventional methods can be achieved. Our proposal is different from existing methods in that no identifiability constraint is required when making inference about $\boldsymbol{\eta}$. Another merit is that our method can provide estimates of $\boldsymbol{\eta}$ at the same time.

Below we discuss some extensions and limitations of this work.

1. We have developed our method under the normal model and logistic model, due to the data structures of our motivating examples (binary Y in the EEG data and continuous Y in the PSQI data). Our method can also be extended to Poisson regression for count Y: $Y|(Z, \boldsymbol{M}) \sim \text{Poisson}(E(Y|Z, \boldsymbol{M}))$ with the link function $g(u) = \ln u$. In this case, Theorem 1 is still valid with $\boldsymbol{V}_0 = E[\exp\{\beta(\theta_0)^\top X_i\} X_i X_i^\top]$, and the same testing procedures for (7) and (23) can be directly applied.

2. The matrix-covariate discussed in this work is an order-two tensor, which motivates

the matrix structure of the parameter $\boldsymbol{\eta}$. Tensor-covariate can be found in many applications nowadays. For example, p covariates measured at q time points under k environments corresponds to an order-three tensor (with dimension $p \times q \times k$) for each subject. Statistical inference procedures for GLM with tensor-covariate have been developed in Zhou, Li, and Zhu (2013), where the authors focus on the estimation of the effect size of tensor-covariate, i.e., the corresponding tensor parameter. When the research aim is to test the existence of an association between the response and tensor-covariate, our low-rank based test methods can be extended, provided that a version of the asymptotic property Theorem 1 is developed for tensor-covariate. Another issue is the "low-rank parameterization" for the tensor parameter. For the case of order-two tensor, the representation is unique, while this is not true for higher order tensors. It is of interest to study the effects of different low-rank parameterizations to detection power in a future study.

3. In Theorem 1, we have established the asymptotic property of $\widehat{\beta}$ with fixed (p, q) and diverging n. Since the number of effective parameters of the rank-r GLM is $s_r = O(pr + qr)$, one only requires $n \gg s_r$ (instead of $n \gg 1 + m + pq$) when applying Theorem 1. The large difference between s_r and $1 + m + pq$ demonstrates the applicability of Theorem 1 (and the proposed test methods) in various situations, where conventional asymptotic result under model (3) can be infeasible (i.e., the case of $1 + m + pq \gg n > s_r$). Theorem 1, however, can be problematic when both (p, q) are larger than n. It is thus of interest to extend Theorem 1 to the case of diverging

(n, p, q). This issue is beyond the scope of this work and can be a future study.

Supplementary Materials

The online supplementary material containing the proof of Theorem 1 can be found on the website of the journal.
